Preface

This book comprises the forty-second volume of the Annual Transactions of the American Institute of Electrical Engineers. It consists almost entirely of papers and discussions presented at the four national meetings of the Institute during 1923 and its makeup and size follow the style first adopted with the 1922 volume. All of the material contained in this volume has appeared in the monthly JOURNALS of the A. I. E. E., except that certain of the longest papers were printed in abridged form in the JOURNAL, whereas they are given complete in this volume. The amount of material presented before the Institute during this year has been so large that it was found impossible to reproduce all of it in this volume, owing to the necessary limitations of size and expense. It has therefore been a matter of grave consideration for the Publication Committee to select from the year's production of papers those which were considered of greatest value for reference purposes and to eliminate such papers as might be considered of more transitory interest. The JOURNALS of the A. I. E. E. for the year corresponding to these TRANSACTIONS also contain numerous contributions of merit which have been omitted from the TRANSACTIONS merely for lack of space. In order to make these contributions and the eliminated Institute papers available to the membership, they have been included in the index of the TRANSACTIONS, referring to the issues of the JOURNAL in which they were published. The arrangement of the articles in this volume is generally chronological and each group or groups of papers is followed directly by the discussion thereon. The contents of this volume are indexed both by title and author's name and are cross-indexed wherever possible. In addition to the index of authors, the names of all those taking part in the discussions are also included. The volume concludes with the annual report of the Board of Directors for the fiscal year ending April 30, 1923, together with the officers, committeemen, and Section and Branch officers for the corresponding year.

of breakdown than the stress at the surface of the dielectric, it seems hard to support the minimum stress theory.

In all the theories which have been advanced so far, it has been assumed that the dielectric strength of the dielectric in a cable is a constant and independent of the shape of the electrodes after taking into account the shape of the electrostatic field for computing the dielectric strength from the theoretical law. Why is it not fair to assume that the dielectric strength as computed is not what we commonly called the "true dielectric strength" of the dielectric but really the "apparent dielectric strength?" That is, we mean the true dielectric strength must be corrected for the shape and size of the electrodes and that this correction factor will give us a means of obtaining a constant which we can call the true dielectric strength of the dielectric.

There are grounds for making the above assumption. We know that if a dielectric is tested for breakdown strength between parallel plates, it is necessary to state the size of the electrodes and the thickness of the dielectric or the results are not of great value. Mr. F. M. Farmer⁷ in a very valuable paper shows this to be true. The writer believes from tests he has conducted that the dielectric strength of a dielectric when tested between parallel plates is a constant, provided a correction factor is used. Here again it is a question of true or apparent dielectric strength. This correction factor is very nearly the correction factor for the increase in capacity between two parallel plates due to end effect.

Knowing that the dielectric strength for parallel plates is a function of the area and thickness of dielectric, suppose we assume that the dielectric strength of a cable is a function of the *radii* or surface of the conductor and sheath.

The writer, in 1914 and 1915, conducted a research⁸ on the present problem. The same methods were used as described in the Middleton, Dawes and Davis paper, that is, samples of cables were studied with constant conductor diameter and variable sheath diameter and variable conductor diameter with a constant sheath diameter. Instead of using the commercial kind of dielectric, ceresine wax was used, as it is more homogeneous than rubber, paper or varnished cambric, could be obtained free of impurities and absorbs practically no moisture.

It was possible to explain the results obtained by means of ionization. Although a great many investigators do not believe in free ions in solids, if we assume they do exist and then apply the laws of ionization, it is remarkable how well computed results agree with experimental data. If we take the law of corona for

air about a wire and apply it to a solid insulation (with the proper constants), we can express the dielectric stress at the surface of a conductor in a cable in a form which will give good agreement between computed and experimental values. This corona law is:

$$K = K_0 \left(1 + \frac{a}{\sqrt{r}}\right)$$

where r is the radius of the conductor, a is a constant, K_0 is the true dielectric strength of the dielectric, and K is the apparent dielectric strength of the dielectric. K is the value which should be used when computing the breakdown voltage of a cable having a conductor radius r .

At the time of the research, the writer had only his own data to study and, consequently, was only able to apply the ionization theory to his data. Since the publication of the recent papers, a further study has been made along the lines described above and the empirical law

$$K = K_0 \left(1 + \frac{a}{\sqrt{r}}\right) \sqrt{R}$$

has been found to express the value of K in the cable formula

$$V = K r \ln R/r$$

This formula for maximum stress states that the dielectric strength of a dielectric in a cable is a function of the radii of the conductor and insulation. If we hold the radius of the conductor r constant and increase the radius of insulation R , K will increase on account of the term $\sqrt{R}$. If we hold the radius of insulation constant and decrease the conductor radius, K will increase. We know from data presented that this is so.

If we should plot $K/\sqrt{R}$ as ordinate against $1/\sqrt{r}$ as abscissas, the value of $K/\sqrt{R}$ for various values of $1/\sqrt{r}$ should fall along a straight line.

Let us now compare the four different viewpoints, namely, the minimum stress, the average stress, the increase in conductor diameter theory when $R/r > 2.72$ and the ionization theory.

Table I gives the value of dielectric strength computed for each viewpoint for the data given in Table II of Fernie's paper. The minimum stress seems to apply very well, considering experimental data. The average stress, although giving a good average deviation from an average stress value, does not seem to apply, as the average stress is decreasing with a decrease in the ratio R/r , whereas it should be independent of ratio R/r . For the ionization theory, the equation for K maximum was found by plotting $K/\sqrt{R}$ against $1/\sqrt{r}$ to be

$$K \text{ maximum} = 131.6 \left(\frac{1.935}{\sqrt{r}} - 1\right) \sqrt{R} \text{ kv. per cm.}$$

Taking this formula, the value of K maximum was calculated with the results given in column 7. A comparison of columns 6 and 7 gives an idea of the

agreement between K maximum actual and K maximum calculated, assuming the corona law to hold. The average difference between K maximum actual and K maximum calculated is 8.6 per cent, which compares favorably with the average deviations of minimum stress and average stress. The Middleton theory gives less values for K_1 than K maximum, as computed from the formula. The stress is not constant, decreasing with a decrease in ratio R/r .

Table II contains an analysis of the various views for the data given in Table III of Fernie's paper. Both the minimum and average stress theories apply well here. The Middleton theory again gives decreasing values of stress with a decrease in ratio R/r . Attention is directed to the very close agreement of K maximum actual and K computed from $K_1 = 5.44 V/D$. The equation for K maximum for ionization theory is

$$K \text{ maximum} = 40.0 \left(\frac{3.29}{\sqrt{r}} - 1 \right) \sqrt{R} \text{ kv. per cm.}$$

Column 7 gives the calculated value of K maximum, using this equation. The average difference between Columns 6 and 7 is 5.2 per cent, which is slightly better than the average deviations for minimum stress and average stress.

Table III is a reproduction of Table I in the Middleton, Dawes and Davis paper. As in the case for the two previous tables, this table gives a comparison of the values of K for the different views. The minimum stress and average stress theories do not hold. The

value of $K_1 = \frac{5.44 V}{D}$ increases as the ratio R/r de-

creases. The samples tested had a constant diameter of insulation D . Therefore, we should expect a curve similar in shape to curve $A B C$ in Fig. 2 of their paper. Fig. 3 of their paper shows the points to be widely scattered and the curve lies between the theoretical curve as computed by the logarithmic law, and a curve similar to $A B C$ of Fig. 2. Although allowance must be made for deviations of points from true values, still it seems as if we should get better agreement than they present.

Turning now to the ionization theory, Column 7 gives the calculated value of stress after finding the equation

$$K \text{ maximum} = 710 \left(1 + \frac{0.1832}{\sqrt{r}} \right) \sqrt{R} \text{ volts per mil}$$

Fig. 1 is a plot of $K \text{ maximum}/\sqrt{R}$ against $1/\sqrt{r}$ to

show how the points fall along a straight line. This is given in order to compare with Fig. 11 of their paper which shows K maximum plotted against D/d as a straight line. Column 8 gives the per cent difference between columns 6 and 7. It shows a variation plus and minus and an average difference of 4.2 per cent, which is a good agreement for experimental data.

Table IV is the same as Table II of the Middleton, Dawes and Davis paper. The minimum stress theory does not hold. There is a constantly increasing value of average stress with decrease in ratio R/r but not of great amount. The average value is 243 volts per mil with a deviation from the average of 6.6 per cent. The authors in their paper state their empirical law, $K_1 = 5.44 V/D$ does not hold. In this case K_1 decreases with a decrease in R/r . Column 7 gives the calculated value of maximum stress, using the formula

$$K \text{ maximum} = 149.2 \left(\frac{2.02}{\sqrt{r}} - 1 \right) \sqrt{R} \text{ volts per mil,}$$

which was obtained from the straight line plotted in Fig. 1 for K maximum/ $\sqrt{R}$ against $1/\sqrt{r}$. Column 8 gives the per cent difference between columns 6 and 7. The average difference is 4.3 per cent, which is a good agreement and better than the average deviation for the average stress values.

FIG. 1—RELATION BETWEEN RATIO OF CONDUCTOR STRESS TO SQUARE ROOT OF INSULATION RADIUS AND RECIPROCAL OF SQUARE ROOT OF CONDUCTOR RADIUS FOR CABLES IN TABLES III AND IV.

Table V is also taken from the Middleton, Dawes and Davis paper, Table III. The minimum stress and average stress theories do not hold. Instead of using $K_1 = 6.27 V/D$ to compute the stress according to the author's views, the formula $K_1 = 5.44 V/D$ was used. The factor 1.15 has already been used in the development of the formula. This will not detract from the nature of the study as it only gives different values of

K_1 from those presented in their paper. K_1 given in the second last column shows reasonably consistent values with an average deviation from the average of 3.9 per cent. The last column gives the values of K maximum/ $\sqrt{R}$. Here also we get reasonably consistent values with an average deviation from the average of 3.2 per cent or a shade better than 3.9 per cent. It is a question as to which view to choose here. Column 7 gives the calculated value of stress after taking the average value of $K/\sqrt{R} = 3100$ and multiplying it by $\sqrt{R}$ for each point. In view of the small variation in $K/\sqrt{R}$ for each point from the average value, we should expect as good agreement in the calculated value of K maximum.

FIG. 2—RELATION BETWEEN RUPTURING VOLTAGE AND THE RATIO FOR DATA IN TABLE VI

The average difference between actual and calculated values of K maximum is 3.1 per cent, which is very close agreement.

The data in Table VI are taken from the thesis of the writer. Constant diameter over insulation and variable conductor diameter were used. The dielectric strength has been computed for the various viewpoints. Fig. 2 is a plot of V against r/R , taking as a value of K the average of the values of K for ratios $R/r < 2.72$ as was done by Middleton, Dawes and Davis for the data in their Table I. The actual curve for values of $R/r > 2.72$ or $r/R < 0.368$ is slightly higher than the theoretical and more nearly like the theoretical than should be expected according to the Middleton theory. Attention is drawn to the small variation in K maximum over the whole range of values of R/r from 1.198 to 5.35. It would be allowable to take an average of all values and the average deviation is only 2.9 per cent from the average. This is better than the results in any other table. The writer believes this slight change in dielectric strength is due to the greater homogeneity of the dielectric than for dielectrics used by others. It would be fair to state from the values given here that the dielectric strength is a constant and the theoretical law is correct. However, the fact that the dielectric strength decreases with a decrease in ratio R/r causes us to modify the above statement. While studying the data given in the table, the writer found the law $K = K_0 (1 + a/\sqrt{r})$ to apply. It was found recently that the term " $\sqrt{R}$ " would further improve the empirical equation for maximum value of dielectric

strength. Column 6 gives the calculated value of maximum stress from

$$K_{\text{maximum}} = 281 \left(1 + \frac{0.0546}{\sqrt{r}} \right) \sqrt{R} \text{ kv. per cm.}$$

Very close agreement is obtained with the actual value of maximum stress as given in column 5, and the average difference between actual and calculated values is only 0.9 per cent. The minimum stress and average stress theories do not hold.

The writer also conducted tests with a constant diameter of conductor ($2r$) and variable diameter ($2R$)

the geometry of the cable, for example, with d , D or D/d . This is necessary, as in its present form the formula cannot be used to determine beforehand the breakdown voltage of a cable, unless previous data had been obtained for the cable.

The ionization theory has been applied satisfactorily to all the data available. Two assumptions were made in developing the theory; first, ionization takes place in a solid dielectric and the dielectric should follow the laws of ionization; and, second, the dielectric strength of a dielectric is a function of the size and shape of the electrodes, in the case of cables it being found a function of the square root of the radius of the dielectric.

over insulation. The results are not given here because the values of maximum dielectric strength decreased with increase in ratio R/r and none of the previously expressed views were applicable.

Considering the data which have been presented, it does not seem possible to state that the minimum stress theory and the average stress theory will explain the difference between experimental and computed values of voltage breakdown of a dielectric when used in a cable.

The empirical law, which states that the voltage breakdown is a function of the diameter over the insulation when the ratio of diameter over insulation to a conductor diameter is greater than 2.72 and that the dielectric within a diameter the value of which is $D/2.72$ does not add to the insulating properties of the conductor, seems to have some foundation. Further investigation along this line is desirable and in conjunction with the investigation the writer suggests a

study be made of the variation of $K_1 = \frac{5.44 V}{D}$ with

The law $K_1 = 5.44 V/D$ is limited in its application to cables having ratios of R/r greater than 2.72.

The law $V = K_0 \left(1 + \frac{a}{\sqrt{r}} \right) \sqrt{R} r \log R/r$ is ap-

plicable to all ratios as shown very clearly in the tables. It may therefore be considered as a more general formula than $K_1 = 5.44 V/D$. The term $r \log R/r$ of the mathematically developed law is retained which is the term involving the shape of the electrostatic field.

What has been considered the dielectric strength of the dielectric is not the "true dielectric strength" as was supposed, but an "apparent dielectric strength" which is a function of the radii of the conductor and insulation, as was originally assumed.

This new viewpoint is given with the hope that others may consider it in connection with any data they may have and perhaps in time, from the various viewpoints, a correct understanding of what we mean by the "dielectric strength of a cable" will be found.

senting data and the writer apologizes for not including this information in the paper. The tests given in Table VI from the writer's previous work were made at room temperature and an increase of voltage of about 1000 volts per second. We all admit that very long time constant voltage tests when the voltage is near the rupturing voltage and varying temperatures give different results than short time voltage tests and constant temperature.

The writer is unable to appreciate Mr. Del Mar's remark that "it is probable that a solid or semi-solid dielectric would never breakdown under stress if it were absolutely homogeneous." The writer agrees with Mr. Del Mar that it is necessary to conduct many tests before we can feel we have solved the problem in question. However it is necessary to make a start at drawing conclusions after a reasonable number of tests have been made. The data presented by Messrs. Middleton, Dawes and Davis are the results of many tests at each point and the data given by the writer in Table VI are the result of at least 10 tests at each point. The average deviation for each point was low and therefore the average value could be accepted as representing as well as experimental work was possible, the phenomenon taking place for the conditions under test.

Considering the agreement which the new formula gives between computed and actual values of K for each of the tables given in the paper and the fact that all but five of the tables were taken from papers by authors and on different dielectrics gives the formula more weight and that there may be something more worth while in it than Mr. Del Mar seems to believe. Very true, ceresine and impregnated paper exhibit totally dissimilar characteristics and this is brought out in the expression $K = K_0 (1 + a/\sqrt{r} \sqrt{R})$. The dissimilarity would be shown in the value for a , K and whether a positive or negative sign would occur. The baffling effect referred to by Mr. Del Mar is due to the higher amount of free ions and the greater freedom of mobility of ions in petrolatum than in paper. Change the freedom of mobility in paper and you will change the characteristics of impregnated paper.

I am very glad Mr. Del Mar reports evidence of free ions in petrolatum. It helps to substantiate what the writer has believed for many years. The writer views the problem as to what is a dielectric, as follows, all substances, gases, liquids, and solids have free ions, different substances having different amounts and each substance having a different mobility, both of which determine the dielectric strength of the substance. The number of free ions in gases is large and freedom of motion great, therefore we get low dielectric strength. Liquids may be classed as the next higher order of dielectric, having less free ions and less mobility than gases. Solids present the case of where free ions are few and freedom of motion greatly limited, resulting in high dielectric strength. The above refers to homogeneous materials. Where we have a non-homogeneous substance such as rubber each of the pure substances in the rubber has its own influence on the resulting material. For a substance like impregnated paper in a cable we have the combination of liquid, and paper impregnated with a liquid. The liquid alone has a property of its own but the impregnated paper is a combination of liquid and the solid paper. The resulting material may have any number of characteristics as the liquid and paper alone and in combination vary. It may even happen that for the same liquid and paper, two cables may exhibit different properties on account of some slight change in the treatment or manufacture which would change the ionic characteristics of each dielectric.

The writer appreciates greatly the remarks of Mr. Shanklin in referring to the views of Dr. Steinmetz, Dr. Wagner and Messrs. Peaslee and Peek. The writer's paper was written in August, 1922 prior to the publication of Dr. Wagner's paper and the discussion of the papers presented at the Niagara Falls Convention.

Without being too bold, since reading Dr. Wagner's paper and the remarks of Mr. Peaslee the question has arisen in the mind of the writer, are we all referring to the same thing? Is Dr. Wagner's conduction breakdown theory and Mr. Peaslee's ideas the same as the views expressed by the writer but expressed differently. They view the subject from a changing conduction angle whereas the writer looks upon it as an ionization phenomenon. Corona such as we call the visible glow in air when the ionization becomes great enough to make the air conducting is not necessary before we say ionization takes place. Mr. Bergen Davis¹ in a paper presented before the Institute in 1914 showed that ionization and corona are practically identical. Some of his ideas present a good foundation for a study of the phenomenon of ionization. Ionization in gases takes place as soon as the voltage stress is great enough to cause the free ions to move and create other ions by impact. It seems reasonable to suppose that the same will be true for the free ions in a solid. Furthermore it is not necessary that there be any physical effects resulting from the formation of ions in the dielectric. If we agree to these statements, then it is not so difficult to explain some of the phenomena of the electrical breakdown of dielectrics. Taking Mr. Peaslee's discussion of the papers presented at the Niagara Convention. Is the current he refers to partly the current due to ionization and not entirely a conduction current obtained from resistance? As the voltage increases and therefore the voltage stress, any free ions present will be set in motion, causing other ions to be formed by collision with neutral molecules. These ions are moving toward the positive electrode to be discharged. If the positive electrode is near the negative electrode, the ions will be discharged, and a further increase in voltage stress is necessary in order to produce a sufficient number of ions to cause the dielectric to become conducting by breakdown. If the positive electrode is not close to the negative electrode the ions do not have time to reach the positive electrode before a large number have been produced in the region of the negative electrode. This may result in the dielectric around the negative electrode exhibiting the properties of a conductor and the electrode has been virtually extended into the substance of the dielectric. This will result in a greater increase in the number of ions without further increase in voltage and finally, puncture will occur. The voltage necessary to cause breakdown will not be proportional to the voltage required for small distances between the electrodes. In the case of alternating voltages, there is the additional consideration that the time phase is likely to change before the ions have been able to discharge, so that they will simply accumulate around the electrodes and the dielectric will become conducting at the electrodes with the results previously stated. Is the current Mr. Peaslee refers to at different parts of the insulation the ionization current described above. The writer believes it is and that his curve of current density can be explained by ionization of the dielectric as the voltage is increased.

It may be of interest in connection with Mr. Shanklin's reference to "energy distance" to report that calculations were made for the data given in the paper with the following results.

The value of the voltage stress was computed at a radius equivalent to that for the energy distance as found by means of the ionization formula for each table. The voltage stress at the energy distance should be constant. The following average deviation was found for each table.

Table	I	II	III	IV	VI
Average dev. per cent.	10.4	6.0	0.1	7.6	0.3

For Table I, II and IV, the formula for K had a negative sign, whereas for Table III and VI, the formula for K had a positive sign. Although a constant value of K was not obtained for the stress at the energy distance for each table, in two cases it was practically obtained and for the other three, fair agreement obtained.

1. Theory of Corona, by Bergen Davis. PROCEEDINGS, A. I. E. E., Vol. 33, April, 1914.

Experimental Determination of Short-Circuit Currents in Electric Power Networks

BY O. R. SCHURIG

Member A. I. E. E.

General Electric Co., Schenectady, N. Y.

Review of the Subject.—No means has yet been discovered whereby the abnormal rise of current occurring during short circuits is avoided. Protection against its destructive effects remains, therefore, a subject of major importance. Among the problems requiring short-circuit current determinations, the following are the chief ones:

(1) Selection of oil circuit breakers of the required interrupting capacity.

(2) Determination of the size of current-limiting reactors.

(3) Determination of relay settings in relay systems depending on selective action from over-current and directional relays.

(4) Calculation of mechanical stresses in the structural elements of apparatus subject to short-circuit electromagnetic forces.

Each of these problems requires the knowledge of the magnitude of short-circuit currents; relay problems frequently require, in addition, the relative phases of currents and voltages at different points of the system during short circuits; in item (4) above the wave-form of the short-circuit current sometimes has to be considered. The available information on the latter subjects, *i. e.* on phase relations and on wave form during short circuits is relatively meager, probably because it has been required in special cases only. Nevertheless, the demands for these data are increasing—on account of both the tendency towards increased sensitiveness of protective

devices and the rapid increase in the magnitude of the short-circuit currents to be handled—and it will be worth while, therefore, if this added information is obtained. This paper is confined to the problems of the determination of the magnitude of short-circuit currents.

The magnitude of short-circuit currents depends on a multiplicity of factors which have been enumerated and dealt with in other publications.¹ When the impedances of all the circuit elements affected by the short-circuit are known together with the current-time decrement characteristics of all machinery capable of supplying current to the short circuit,² the problem of short-circuit-current determination resolves itself into one of current division in a given network of electrical conductors under given electromotive forces.

In the following paper, the comparative merits of three methods—calculation, a-c. test, and d-c. test—of determining short-circuit currents in networks are briefly discussed. Two d-c. experimental methods applicable to the "short-circuit calculating table" are analyzed in detail. The accuracy of its results, by both methods, is obtained for a variety of circuit conditions. The proper field of use of the short-circuit calculating table, and the best method of its application are determined.

2. See Bibliography No. 1, 2, 3.

INTRODUCTION

SHORT-CIRCUIT currents in networks may be determined by calculation from the circuit constants and the connection diagram, or by tests with an experimental circuit equivalent to the system under consideration. The calculations for complicated networks by the elementary procedure using Kirchhoff's law without employing simplifications or mathematical shortcuts are extremely lengthy and not practical. Although the complications are reduced by the use of circuit transformations and by mathematical methods,³ test methods in many cases give quicker results of sufficient accuracy for routine short-circuit-current determinations.

The most obvious test method is that in which all the essential elements in the system under consideration are reproduced in a miniature system in true proportion. This kind of test calls for a miniature a-c. system. The chief disadvantages of this type of a-c. test system are due to the necessity of both resistor and reactor units and to the limitations of the low-range a-c. meters: the miniature apparatus has to be either of relatively large current rating to accommodate the available a-c. instruments and thus becomes quite expensive, or delicate low-range instruments are required. These conditions have brought about the d-c. miniature line in the form of the short-circuit calculating table. Its

use is based on an approximation whereby the complete a-c. system under short-circuit conditions is reduced to an approximately equivalent d-c. network. The magnitudes of the currents in the various circuit branches of this equivalent d-c. system under short-circuit are determined by test, and converted by the use of the proper factor of proportionality into the corresponding a-c. currents of the original system.

One method of employing this short-circuit calculating table is to make the ohmic resistance values in the equivalent d-c. system proportional to the reactances of the various circuit elements, *i. e.* of generators, reactors, transformers, lines, etc. This method may be called the *reactance method*.

The second method of applying the short-circuit calculating table is the *impedance method*, in which the impedances in all the system elements are assumed to be in phase and set up as resistances on the calculating table. This method is not in general use.

The details of construction of this apparatus and the customary method of its application have been fully described in several publications.⁴

OBJECT

It is the object of this paper to determine the merits and limitations of the short-circuit calculating table,

4. Descriptions of several forms of short-circuit calculating table are found in the following articles: Bibliography No. 7, 10, 11, 12 and 13. For reference to the reactance method of short-circuit-current determination, see Bibliography No. 8, 9 and 13.

3. See Bibliography No. 4, 5, 6.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 14-17, 1923.

Underground cable systems

Systems having both aerial conductors and underground cables.

Systems of Aerial Conductors. The error most readily determined is that due to the impedance angles of generators and of distribution lines. When all the principal lines affected by a short circuit have equal impedance angles, these lines may for this purpose be consolidated into one equivalent impedance of the same angle. When, furthermore, in such circuits all sources of short-circuit current may be replaced by one equivalent generator, all short-circuit currents will have the same error. Circuits of this type will be considered first. The resistance of generators, when of the order of 1/20 of their reactance, will be neglected.

The examples given apply to three-phase systems, and the resistance and reactance data are the values per conductor. Three-phase short-circuits are considered.

Example 1

Series circuit consisting of generating station, transformer bank and aerial conductors, all in series; reference kv-a. = 11,000.⁹

Resist. ⁹ per cent	React. ⁹ per cent	Imped. per cent
-------------------------------------	------------------------------------	-----------------------

Generators, total capacity 11,000 kv-a.; 6600 volts, 60 cycles, 3-phase.....	..	28.0	28.0
Transformer bank 6.6/44 kv.....	0.9	4.8	4.9
Lines 44 kv., of 116,000 cir. mil copper and of 179,000 cir. mil aluminum; total resistance and reactance of lines to point of short circuit 124 miles from generating station, all lines hav- ing practically the same impedance angle.....	16.5	31.0	35.1/62

Total impedance of all circuit elements = $17.4 + j 63.8 = 66.1$ per cent.

Scalar sum of all impedances = 68.0 per cent.

Hence the error of the short-circuit current by the reactance method is indicated by the ratio $u_x =$

$$\frac{66.1}{63.8} = 1.04, \text{ meaning that the result is 4 per cent high.}$$

The corresponding error of the impedance method, obtained from the impedance accuracy factor $u_z =$

$$\frac{66.1}{68.0} = 0.97, \text{ is 3 per cent low.}$$

9. It is often convenient to express resistance and reactance in terms of the per cent voltage drop through them; i. e. the percentage reactance drop—frequently called briefly the “per cent reactance”—is the voltage drop, expressed as a percentage of normal voltage, across the reactance when traversed by a current due to a specified balanced kv-a. load on the circuit. If x is the reactance in ohms, kv-a. the reference kv-a., and kv. the line voltage in kv. in a 3-phase circuit, the “per cent reactance” is per cent $x = \frac{x (\text{kv-a.})}{10 (\text{kv.})^2}$ (see Bibliography No. 9).

NOTE: The accuracy factor u_x is the ratio of short-circuit current by reactance method to the correct short-circuit current; u_z is the corresponding ratio applied to the impedance method.

It is seen that the error of the short-circuit current by the reactance method is not excessive and is on the safe side. The chief source of error is the resistance of the lines. It should be noted that the impedance angle of the lines is 62 deg., while that of generators and transformers is substantially 90 deg.

Example 2

A three-phase generating station with transformers supplies a 110-kv. 60-cycle aerial line. Reference kv-a. = 60,000.

	Resist. per cent	React. per cent	Imped. per cent
Generators, 60,000 kv-a. aggregate rating, total combined reactance..		12.0	12.0
Transformer unit, 13.2/110 kv., 20,000 kv-a. rating.....	1.5	19.4	19.4
Line, 110 kv., 250,000 cir. mils copper short-circuited 88 miles from sta- tion.....	10.0	35.9	37.2/74.4

Total impedance of all circuit elements up to point of short circuit = $11.5 + j 67.3 = 68.3$ per cent.

Scalar sum of all impedances = 68.6 per cent.

For the short-circuit current by reactance method,

$$u_x = 68.3/67.3 = 1.015$$

which means that the short-circuit current is 1.5 per cent high. Likewise, for the impedance method

$$u_z = 68.3/68.6 = 0.996$$

which means an error of 0.4 per cent low. The errors of the short-circuit current are seen to be negligible.

Example 3

One 60-cycle, 3-phase generating station with transformer bank; circuits affected by short-circuit: two series-connected aerial lines fed from the generating station; reference kv-a. = 25,000.

	Resist. per cent	React. per cent	Imped. per cent
Generators with transformers 13.2/88 kv. aggregate rating 43,750 kv-a., impedance components of entire station.....	0.5	13.3	13.3
Line 88 kv. No. 1/0 B & S copper, 29 miles.....	4.8	8.1	9.5/59.4
Line 88 kv. No. 1/0 B & S aluminum, 51 miles.....	13.9	13.3	19.3/43.8

Both lines in series, point of short-circuit 80 miles from generating station.

Total impedance of all circuit elements up to point of short-circuit = $19.2 + j 34.7 = 39.7/61.0$.

Scalar sum of all impedances = 42.1 per cent.

For the short-circuit current, by reactance method

$$u_x = 39.7/34.7 = 1.14$$

which means that the short-circuit current is 14 per cent high. Likewise for the impedance method

$$u_s = 39.7/42.1 = 0.94$$

which means that the error is 6 per cent low. The somewhat greater errors in this case are caused by the following factors: The impedance of the distribution lines between the generating station and the point of short-circuit has a fairly low angle (49 deg.) and a relatively large magnitude (more than twice that of the generating station impedance); in other words, the circuit elements of low impedance angle constitute the larger part of the total system impedance. This example illustrates the accuracy of the short-circuit current by the calculating table for a fairly remote short-circuit on a system having distribution lines of an impedance angle in the vicinity of 45 deg.

Example 4

Occasionally the distribution lines of a system have dissimilar impedance angles. This condition may arise from the use of unequal wire sizes, or of dissimilar metals, or of reactors. In the example chosen, a generating station with step-up transformers feeds two aerial lines, of unequal wire sizes, connected in parallel and terminating in a common bus. The data are as follows: Reference kv-a. 15,000, frequency 60 cycles.

	Resist. per cent	React. per cent	Imped. per cent
Generators with step-up transformers total generating capacity 26,000 kv-a.	0.60	9.20	9.21
Line No. 1, 38 miles long, No. 2 B & S copper, 60 kv.	13.70	13.10	18.95/44
Line No. 2, 38 miles long, No. 4/0 B & S copper, 60 kv., connected in multiple with line 1.	4.25	11.80	12.55/70

Short-circuit at terminal of lines.

By calculation from these data, by the customary method, the errors of the total short-circuit current and of the branch currents in lines No. 1 and No. 2 are as follows:

	Reactance Method	Impedance Method
Total short-circuit current.	7 per cent high	1 per cent low
Branch current 1.	24 per cent high	4 per cent low
Branch current 2.	9 per cent low	4 per cent low

It is seen that the total current by the reactance method is not badly in error and is on the safe side, while the branch current No. 1, is 24 per cent high. It will be observed that the reactance method gives a high result for the branch of low impedance angle, (44 deg.), and a low result for the branch of higher impedance angle, (70 deg.), while the impedance method gives equal errors (only 4 per cent low) in the two parallel branch lines.

The results of the preceding four examples may be summarized as follows: In examples 1, 2 and 3, systems

having distribution circuits of the same impedance angle were considered. The errors of the reactance method were on the safe side in all cases (*i. e.* high results); in the first two cases the error was below 5 per cent, but in the third case the error was 14 per cent because the distribution lines had impedance angles of the order of 45 deg. and impedance magnitudes amounting to as much as two thirds of the total system impedance. In the fourth example, one of occasional occurrence, parallel circuits of widely dissimilar impedance angles gave by the reactance method a permissible error for the total short-circuit current, but an error of slightly over 20 per cent for one of the branch currents. The impedance method gave low values in this case, but none more than 4 per cent in error. The conditions illustrated by examples 3 and 4 are considered in detail in the more general analysis presented later.

Systems of Underground Cables. Cables generally have lower impedance angles than aerial lines. When short circuits occur near a generating station, the impedance limiting the short-circuit current is largely due to the generators and station reactors and therefore has a large angle. The total short-circuit current, as determined by the calculating table, will then not be badly in error. The minor components of short-circuit current in the longer cable lines may however have greater errors. Similarly for remote short circuits the impedance angle of the cables may materially lower the accuracy of the total short-circuit current.

The case of a near short circuit on a cable system having No. 4/0 B & S 3-phase, 3-conductor, 15,000-volt cables, at 60 cycles, will be illustrated by the following example:

Example 5

Reference kv-a. = 40,000

	Resist. per cent	React. per cent	Imped. per cent
Generating station.	0.50	16.5	16.5
Combined data for cable circuits between generating station and point of short circuit; this im- pedance is equivalent to that of two parallel No. 4/0 B & S 15,000 volt 3-phase cables, each one mile long.	3.06	1.55	3.43/27 deg.

The total circuit impedance to the point of short circuit is

$$3.56 + j18.05 = 18.4 \text{ per cent}$$

The scalar sum of the circuit impedances is 19.9 per cent. Hence, we have by the reactance method

$$u_s = 18.4/18.05 = 1.02$$

or an error of 2 per cent (high). Likewise, by the impedance method,

$$u_s = 18.4/19.9 = 0.92$$

representing an error of 8 per cent (low).

Example 6

In this example, the system of example 5 will be considered, but the short circuit will be located remote from the generating station, such that the combined impedance of the cable circuits between generating station and point of short circuit is equivalent to 2.5 miles of No. 4/0 B & S copper 3-conductor cable. Using 40,000 kv-a. as the reference kv-a. the data are,

	Resist. per cent	React. per cent	Imped. per cent
Generating station.....	0.50	16.5	16.5
Combined data for cable circuits between generating station and point of short circuit.....	15.3	7.75	17.15/27 deg.

The total impedance to the point of short circuit is
 $15.8 + j 24.3 = 29.0$ per cent

The scalar sum of the circuit impedances is 33.7 per cent.

Hence, by the reactance method,

$$u_x = 29.0/24.3 = 1.19$$

representing an error of 19 per cent high. Likewise by the impedance method:

$$u_z = 29.0/33.7 = 0.86$$

representing an error of 14 per cent low.

Example 7

In this example, the network shown in Fig. 1 will be considered. The data given in this diagram and in Table I are miniature test data representing an 11,000-volt, 60-cycle underground 3-conductor cable system, having current-limiting reactors (giving a 3 per cent voltage drop in the cables when carrying full-load cable current) in each of the lines A, B, C, D, E. The cables are of No. 4/0 B & S and 250,000 cir. mil copper. Those in lines F, G, H, and I have no reactors, and therefore have low impedance angles, of the order of 26 to 31 deg. The results by a-c. test, by reactance and by impedance methods, are given

in Table I, for a 3-phase short circuit at b. The total short-circuit current by reactance method is 5 per cent high, that by impedance method is 4 per cent low. These errors are small because the impedance angle of the cable network from generator bus to the point of short-circuit is 56 deg. The three principal components, B, C and F of current fed into the short circuit have errors, by the reactance method, from 7 per cent low to 16 per cent high, the negative error occurring in B, i. e. in the path of highest impedance

FIG. 1—CIRCUIT DIAGRAM FOR EXAMPLE 7

Short-circuit current determination. Arrows indicate direction of short-circuit current. Note: Figures opposite lines and generator represent resistance and reactance values, expressed as complex numbers; line-to-neutral values in ohms per phase. Reactance of reactors included with line impedances for lines A, B, C, D, E.

angle (67 deg.). The current in line F (error 16 per cent high) is partly dependent on reactances of lines having low impedance angles (as low as 26 deg.). Errors of over 20 per cent high, by reactance method, occur in three lines more remote from the point of short circuit. However, these lines have the lowest currents, each carrying less than 15 per cent of the total short-circuit current, and two of them are over four miles long.

The short-circuit currents by the impedance method have a maximum error of 6 per cent low. In this

TABLE I

Circuit constants and miniature test data for short-circuit current determination in cable network of Fig. 1. The data given represent in true proportion the conditions of the actual network. The ohmic values given are 56 times the actual system values.

	Length miles	Miniature circuit data			Miniature a-c. test short-cir't. current amperes	Reactance Method		Impedance Method	
		Resist. ohms.	React. ohms	Impedance ohms		Short-circuit current	accuracy factor	Short-circuit current	Accuracy factor
gen.		—	26.1	26.1 /90	9.70	10.13	1.05	9.27	0.96
A	3.1	47.5	76.2	89.8 /58.1	1.30	1.550	1.19	1.218	0.94
B	2.1	26.3	62.0	67.3 /67.0	2.96	2.765	0.93	2.875	0.97
C	3.3	42.6	71.9	83.5 /59.3	2.37	2.385	1.01	2.320	0.98
D	2.4	32.0	65.1	72.5 /63.8	1.88	1.99	1.06	1.761	0.94
E	4.1	62.3	84.9	105.3 /53.7	1.17	1.438	1.23	1.098	0.94
F	1.1	13.84	8.34	16.20 /31.1	4.28	4.98	1.16	4.075	0.95
G	0.7	10.26	4.95	11.4 /25.7	1.21	1.507	1.24	1.145	0.95
H	1.0	13.76	7.40	15.6 /28.3	1.25	1.480	1.18	1.172	0.94
I	5.9	100.8	50.7	112.8 /26.7	0.05	0.069	1.4	0.047	0.94

NOTE: The reactance and impedance values for lines A, B, C, D and E include the reactances of cables and of the reactors in series with the cables.

This circuit condition, while somewhat unusual, serves to illustrate the magnitude of the errors that may arise from the use of the reactance method in systems having parallel connected circuit elements of widely dissimilar impedance angles. The circuit construction of Fig. 3 has the disadvantage of giving large interchange currents in normal system operation and is, therefore, not common.

ANALYSIS OF CIRCUITS

From the preceding examples it is seen that, for the determination of the accuracy of the short-circuit calculating table, electric power systems may be divided into two classes:

(a) those systems in which the circuit elements of dissimilar impedance angles occur in series connection

FIG. 3

Full vertical lines indicate 10,000-volt 3-conductor cables. Dotted lines indicate 50,000-volt aerial 3-phase circuits. All impedances are expressed in ohms with their impedance angles. Impedances of circuits A and J include transformer impedances.

only; i. e. all parallel connected circuit elements are of the same impedance angle; systems of this class are illustrated by examples 1, 2, 3, 5, 6, and 8.

(b) those systems in which the circuit elements of dissimilar impedance angles occur in multiple as well as in series. Such circuits are represented by examples 4, 7 and 9.

The following analysis of circuits is made on the basis of this classification.

Systems in which the circuit elements of dissimilar impedance angles occur in series connection only. The simplest circuit of this type is that of Fig. 4, in which z_g represents the impedance of the generating station and z_1 represents the impedance of the distribution network to the point of short-circuit, all distribution lines having the same impedance angle. The accuracy of the reactance and impedance methods was determined by calculation of the accuracy factors, as explained in example 1. These factors for the reactance method are plotted in Fig. 5 for a wide variety of circuit constants covering a range of variation of z_g from $0.2 z_1$ to $2.0 z_1$

and a wide range of variation of impedance angle of z_1 from 90 deg. (pure reactance) to 0 deg. (pure resistance). The application of these curves will be illustrated by the following case employing the system of example 6: $z_g = \text{impedance of generating station} = 0.5 + j 16.5 = 16.5/88 \text{ deg.}$

$z_1 = \text{impedance of distribution system to point of short-circuit} = 15.3 + j 7.75 = 17.15/27 \text{ deg.}$

With practically no error, the angle of z_g may be taken as 90 deg. The ratio of $z_g/z_1 = 0.96$. In sheet 5, for an abscissa of 27 deg. the ordinate for $z_g = 0.96 z_1$ is, by approximate interpolation, 1.19 (i. e. slightly greater than the ordinate for the curve $z_g = z_1$). The error by reactance method is, therefore, 19 per cent high and agrees with the result previously given.

When a system of this type has more than two series-connected portions, all having different impedance

FIG. 4—SERIES CIRCUIT DIAGRAM

FIG. 5—ACCURACY FACTOR

Total current, reactance method. Circuit: A generator supplying a single circuit. Variation of magnitude of Z_g and of angle of Z_1 ; $Z_g/Z_1 = 0.2, 0.5, 1.0$ and 2.0 times Z_1 ; Z_g angle, 90 deg. constant; Z_1 angles, 0 deg. to 90 deg.

angles, the data of Fig. 5 may be applied as long as all parallel-connected circuit elements have the same impedance angle. Example 8 is of this type. This system of five major portions may be reduced to two series-connected impedances, namely:

$z_g = \text{generating station and } T_1 = 0.4 + j 10.0 = 10.0$
 $z_1 = \text{series combination of 110 kv. lines, } T_2 \text{ and 12 kv. cables} = 7.8 + j 10.3 = 12.9/53 \text{ deg.}$

It follows that $z_g = (10.0/12.9) \times z_1 = 0.78 z_1$

Correspondingly, the accuracy factor of the short-

circuit current by reactance method is, from Fig. 5, for an abscissa of 53 deg. approximately 1.08, a value identical with that found by previous calculations.

The shaded parts of Fig. 5 indicate circuit conditions for which errors safely below 20 per cent are obtained by the reactance method in this type of system. Typical circuit conditions resulting in errors within this limit are the following:

Generating station reactance not lower than distribution system impedance and angle of the latter not lower than 30 deg.

Generating station reactance not lower than one half the distribution system impedance and angle of the latter not less than 45 deg.

Generating station reactance not lower than one fifth the distribution system impedance and angle of the latter not less than 55 deg.

FIG. 6—ACCURACY FACTOR

Total current, impedance method. Circuit: A generator supplying a single circuit. Variation of magnitude of Z_G and of angle of Z_1 ; $|Z_G| = 0.2, 0.5, 1.0$ and 2.0 times $|Z_1|$; Z_G angle, 90 deg. constant; Z_1 angles, 0 deg. to 90 deg.

These circuit conditions include the majority of aerial systems and a large number of cable systems.

The results of the impedance method for the same range of series circuit conditions covered by Fig. 5 are given in Fig. 6. The accuracy factors shown indicate low values of short-circuit current. It is seen that the errors for the customary circuit conditions are not consistently smaller than those obtained with the reactance method.

It follows from these considerations that the reactance method is preferable to the impedance method under the circuit conditions stated above (as covered by the shaded portions of Fig. 5), the former method giving values of short-circuit current slightly high, and not necessitating impedance determinations.

Application of Results for Series Type of Circuits.

The determination of the error for systems within this class requires the knowledge of the impedance angle of the distribution system (62 deg. in the case of example 1) and of the ratio of generating-station reactance to distribution-system impedance. The latter ratio is approximately equal to the product of the sine of the distribution system impedance angle times the ratio of generating station reactance to distribution system reactance, the latter being obtained from the test data by the calculating table when completely connected up for short-circuit tests.

Systems in which parallel-connected circuit elements have impedance angles less than 15 deg. apart may be considered as belonging to the class of systems under consideration. It should be pointed out here that a reactor placed between a distribution line and the bus from which it is fed must be considered as a separate circuit element for a short circuit occurring in the line near its junction to the reactor. The reactor will then be in multiple with other impedances, generally of lower impedance angle, if there are other lines feeding short-circuit current from the bus towards the fault. In such cases, the results derived above for series circuits do not apply.

Systems having Multiple-Connected Impedances of Dissimilar Angles. The simple circuit chosen for the consideration of multiple circuits is that of Fig. 7, where z_G represents a generating station (of sub-

FIG. 7—PARALLEL CIRCUIT DIAGRAM

FIG. 8A—ACCURACY FACTOR

Total Current—Reactance Method. Circuit: A generator supplying two parallel branch lines. Variation of magnitude of Z_G and of angle of Z_2 ; $|Z_1| = |Z_2|$; $|Z_G| = 0, 0.2$ and 2.5 times $|Z_2|$; Z_G angle, 90 deg. constant; Z_1 angle, 90 deg. constant; Z_2 angles, 0 deg. to 90 deg.

stantially pure reactance) supplying two parallel impedances z_1 and z_2 . It frequently occurs that part of a network under short circuit consists of a number of impedances of substantially the same angle θ_1 , the remaining portion having impedances of another angle, θ_2 . Networks of this type may be reduced to the circuit of Fig. 7. The accuracy factors were determined by the customary calculations and plotted for the total current I and for each of the branch currents I_1 and I_2 . The circuit conditions covered by the curves so obtained are tabulated in Table II. These circuit

TABLE II

Circuit Conditions Covered by Accuracy Data in Figs. 8, 9 and 10. The Data Apply to Circuits of the Type Shown in Fig. 7.

Fig. No.	Method of short-circuit-current determination	Constants of Generator and of Branch Circuits (Fig. 7)					
		z_0		z_1		z_2	
		Magnitude	Angle	Magnitude	Angle	Magnitude	Angle
8A, B, C..... 8D, E.....	React. method Imped. method	from 0 to 2.5 times z_1	90 deg.	$= z_2$	90 deg.	$= z_1$	from 0 deg. to 90 deg.
9A, B, C..... 9D, E.....	React. method Imped. method	$= z_1$	90 deg.	$= z_2$	from 15 deg. to 90 deg.	$= z_1$	from 0 deg. to 90 deg.
10 A, B, C..... 10 D, E.....	React. method Imped. method	$= z_1$	90 deg.	$= 0.2 z_2$	from 15 deg. to 90 deg.	$= 5 z_1$	from 0 deg. to 90 deg.

conditions include variations of magnitude of generator and branch-circuit impedances as well as variations of impedance angle for each of the branch circuits.

Reactance Method. From an examination of the curves in Figs. 8A, B, C, 9A, B, C and 10A, B, C it is seen that in a number of cases one of the branch currents is low, the current in the other branch and the total current being high. If on account of this fact the error is limited to 10 per cent above or below the correct value, meaning a maximum discrepancy of 20 per cent between branch currents, the reactance method is limited to systems with impedance angles not materially lower than 60 deg., *i. e.* systems having impedance angles ranging from 60 deg. to 90 deg. in parallel-connected circuit elements. The shaded areas in the curves for the reactance method cover this range. When the error limit is 20 per cent, the permissible range of impedance angles under these conditions is from 90 deg. down to about 50 deg. For wider ranges of impedance angle in parallel-connected circuit elements, the errors of the reactance method increase rapidly.

FIG. 8B—ACCURACY FACTOR

Branch current I_1 —Reactance method. Circuit: A generator supplying two parallel branch lines. Variation of magnitude of Z_0 and of angle of Z_1 ; $|Z_1| = |Z_2|$; $|Z_0| = 0, 0.2, 1.0$ and 2.5 times $|Z_2|$; Z_0 angle, 90 deg. constant; Z_1 angle, 90 deg. constant; Z_2 angles, 0 deg. to 90 deg.

Impedance Method. The curves in Figs. 8D, E, 9D, E and 10D, E indicate that some types of systems for which the reactance method gives excessive errors may be solved by the impedance method with better accuracy. The prevailing tendency of the impedance

method is to give low values of short-circuit current. High values occur occasionally but these are only slightly large for impedance angles as low as 30 deg. For an error limit of 15 per cent, indicated by the shad-

Branch current I_2 —Reactance method. Circuit: A generator supplying two parallel branch lines. Variation of magnitude of Z_0 and of angle of Z_1 ; $|Z_1| = |Z_2|$; $|Z_0| = 0, 0.2, 1.0$ and 2.5 times $|Z_2|$; Z_0 angle, 90 deg. constant; Z_1 angle, 90 deg. constant; Z_2 angles, 0 deg. to 90 deg.

ing in Figs. 8D, E, 9D, E and 10D, E, the impedance method is applicable to systems with parallel-connected circuit elements of widely dissimilar impedance angles including angles as low as 30 deg. The following example will illustrate a case of this kind in a circuit similar to Fig. 7. Let the percentage values of impedance be as follows:

$$z_0 = 10. / 90 \text{ deg.}$$

$$z_1 = 10. / 90 \text{ deg.}$$

$$z_2 = 10. / 40 \text{ deg.}$$

where z_1 represents a feeder reactor (the short circuit being just beyond the reactor in a cable), and z_2 the impedance of the other cable paths feeding into the

short circuit from the generator. By the impedance method, the accuracy factor for the total short-circuit current is 1.01 from Fig. 9D. This represents an error of 1 per cent high. For each of the two branch currents, the error is 8 per cent low, obtained from Fig. 9E from the accuracy factor 0.92 measured as the ordinate to the curve for an angle of z_1 equal to 90 deg. for an abscissa of 40 deg.

This discussion leads to the conclusion that for

FIG. 9A—ACCURACY FACTOR

Total current—Reactance method. Circuit: A generator supplying two parallel branch lines. Variation of angles of Z_1 and Z_2 ; $|Z_1| = |Z_2| = |Z_G|$; Z_G angle, 90 deg. constant; Z_1 angles, 15 deg., 30 deg., 60 deg., 90 deg.; Z_2 angles, 0 deg. to 90 deg.

systems not covered by the reactance method but having impedance angles not materially below 30 deg. the impedance method gives errors well below 20 per cent and commonly below 10 per cent. The short-circuit current values are generally low. When parallel-connected circuit elements have dissimilar impedance angles ranging from 90 deg. to angles materially below 30 deg., excessive errors may occur.

Additional Factors. While the results given above were derived from an analysis of the two simple types of circuit shown in Figs. 4 and 7, they do not apply

analysis. This is due to the fact that the sum of the magnitudes of any number of inductive admittances can never be more than 1.414 times their vector sum.

method is applicable to any number of series-connected circuit elements as long as all parallel-connected circuit elements have substantially the same impedance angle.

Likewise, for parallel circuits of three or more multi-

Furthermore, the likelihood of obtaining maximum errors diminishes as the number of parallel connected impedances in Fig. 7 increases beyond two.

The error of currents in low-impedance tie lines interconnecting substations in systems having elements of widely dissimilar impedance angles is likely to be greater than that in the feeders supplying these stations on account of distorted voltage drops (such lines are *F*, *G*, and *H* in Fig. 1).

The currents supplied to a short-circuit from different generating stations may be mutually out of phase. This condition may cause an increase or a decrease of error.

In view of these considerations, it is to be concluded that the error limits established for the circuit constants specified apply primarily to the principal current components from the generating stations, and only approximately to tie-line currents or to minor short-circuit-current components.

CONCLUSIONS

The short-circuit calculating table is a simple practical means of making approximate short-circuit-current determinations in networks. It is applicable to a large variety of electric-power networks.

Its chief field of application is that of polyphase short-circuit-current calculations as employed for the selection of oil circuit breakers, for the determination of relay settings, and for the layout of distribution systems.

It is not generally applicable to phase-to-phase short-circuits or to phase-to-ground short-circuits on account of the unbalanced current division among the phases. These latter problems may be solved by calculation or by a-c. test.

The errors of the short-circuit calculating table are due to the neglect of capacity charging currents and due to dissimilar impedance angles occurring in the various elements of a network. The former error is almost always negligible for polyphase short-circuits, being smaller than 10 per cent for a three-phase short-circuit occurring in an aerial line 200 miles from the generator.

In the following, accuracy data are given. The error limits established for the circuit conditions specified apply primarily to the principal current components from the generating stations, and only approximately to tie-line currents.

In a great many systems the resistance component of all the impedances in the network may be entirely neglected for short-circuit-current determinations. This method, the reactance method, generally gives erroneously high current values. The errors are safely below 20 per cent, and commonly under 10 per cent,

(a) in systems in which circuit elements of dissimilar impedance angles occur in series connection only, (*i. e.* parallel-connected circuit elements have impedance angles less than 15 deg. apart), provided the circuit constants are within a definite range of the following character:

Generating-station reactance not lower than distribution system impedance, and angle of the latter not lower than 30 deg.

Generating-station reactance not lower than one-half the distribution system impedance and angle of the latter not less than 45 deg.

Generating-station reactance not lower than one-fifth of distribution system impedance and angle of the latter not less than 55 deg.

(b) in systems not covered by (a), provided all impedance angles are larger than 55 deg.

The systems covered by (a) and (b) above include the majority of aerial systems and a variety of cable systems.

For systems not covered by the range of circuit conditions defined in (a) and (b) above, but having impedance angles not materially below 30 deg., the impedance method is preferable and gives errors well below 20 per cent and commonly below 10 per cent. The short-circuit current values are generally low. Cable systems with current-limiting reactors in some of the lines come within this class. While the impedance method is particularly suited to systems having parallel-connected circuit elements of widely dissimilar impedance angles within the limits stated, it is not a substitute for the reactance method in systems of type (a) and (b) above.

Acknowledgments are due to Mr. G. B. Phillips and to Mr. A. R. Miller for their assistance in the preparation of the data.

Discussion

R. E. Doherty: I wish to discuss two points bearing upon this paper: One regarding accuracy; the other, regarding the extension of the use of miniature models to determine, in addition to the short-circuit current distribution under steady state, as covered by the present paper, the most desirable feeder connections for normal load transfer; and further, the behavior of stations and generating units under transient state.

Although the impedances of lines, cables, reactance coils, etc., can be calculated with a fair degree of accuracy, the calculated value of *transient reactance*¹ of the generators is not so accurate. It can, of course, be determined with fair accuracy by actual short-circuit tests; but in calculations an error as great as 15 or 20 per cent may be expected in some cases. The principal reason for relatively large errors in the calculated values is the effect of abnormal saturation of local flux paths under short circuit. The phenomenon of saturation is extremely complicated and different types of machine construction involve different degrees of saturation. Hence it becomes very difficult to calculate the result. Therefore, in the calculated, or rather estimated, values of *transient reactance*, such errors as I have mentioned must be expected.

This, of course, is no reason, as may be suggested, why the accuracy of the "calculating table" itself should not be better than 20 per cent. The former source of error is necessary, unless tested results are available; but that is no reason why another *known* error of 20 per cent should be superposed, perhaps in the same direction. I therefore agree with the author that by the proper use of the various curves given in the paper, together with a study of the examples, excessive error from the table itself can be avoided. However, the possible error in generator reactance should be kept in mind, especially in those cases where the external reactance is relatively low.

Another source of error is the set of decrement curves usually applied in this connection. I refer to the Hewlett, Mahoney and Burnham curves. The calculating table gives the "initial" or the "sustained" current, as the case may be. In selecting oil circuit breakers, the time element enters; and if such curves are applied to determine the effect of the time element, that is, the decrease in current due to the transient, the possible error in such curves should be kept in mind. As everyone knows, who has read the Hewlett, Mahoney and Burnham paper, these curves represent the first step in the direction of giving some basis for selection of switches, and combining into a single set of curves, as they do in the interest of simplicity, numerical values covering such wide limits, they must necessarily contain sources of considerable error. These errors, however, are, I believe, usually on the safe side, thus giving current values too high. The point is, that having obtained the "initial" value, perhaps by the calculating table, there is possible further error in applying the decrement curves.

Hence, from the foregoing discussion, error may arise from three sources, namely: The generator reactance, the calculating

table, as the author brings out, and the application of the Hewlett, Mahoney and Burnham curves. It has, therefore, seemed advisable to offer the suggestion that, in the use of the calculating table, these additional sources of error be kept in mind.

What appears to be a promising extension of the application of miniature models is the representation of certain isolated sections of a network, including receiving circuit impedances as well as the feeder impedances, for the purpose of determining the most desirable connections of the feeders. This is usually a compromise between the connection which is the most favorable for copper on the one hand and simplicity, relay settings, etc., on the other. Such an extension would obviously involve the case of both resistance and reactance units and to this extent would be more complicated than the direct-current table. This scheme was proposed by G. M. Armbrust of the Commonwealth Edison Company of Chicago, who is investigating the feasibility of such an outfit.

Referring to the possibility of reproducing the transient phenomena in generating stations under short-circuit conditions, it may be of interest to mention that a study and detail design has been made of a miniature generating system, reproducing in small generators the same relation of momentum, reactance, armature reaction, etc., as exists in the actual large units. It thus appears feasible to represent with a small number of machines a relatively large variety of combinations of units. It may be of interest also that these miniature machines are not a geometrical reproduction of the larger machine on a small scale, since such a machine, even if practically feasible to build, cannot be made to represent the actual machines.

G. M. Armbrust: Direct-current calculating tables have been used extensively in large systems to determine short-circuit currents for use in determining relay settings, design of systems, etc. A high degree of accuracy has been obtained in systems having considerable reactance. There has been some doubt, however, as to how extensively the method could be used on cable systems owing to errors introduced by varying impedance angles of the component parts of the system.

Mr. Schurig's paper clears up much of this doubt, and considerably extends the use of the calculating table by outlining its limitations and defining the probable degree of error under a classification of conditions representing most distribution problems.

The Commonwealth Edison Company of Chicago operates some 900 miles of transmission cable, the system being practically entirely underground. Using Mr. Schurig's method described in his paper, I have checked a number of typical cases on this system and obtained results of a reasonable degree of accuracy, agreeing with his conclusions.

The layout of a system such as this, a combination of network and radial distribution, is determined by economy, limitations due to possible short-circuit currents, and feasibility of relay protection. Theoretically the best transmission economy is obtained by an extensively inter-connected network, but the necessity for limiting short-circuit current to the ability of existing equipment to handle it, makes necessary considerable sectionalizing of the system. Determination of the economical design with this limitation requires the solution of many such cases having a wide variation of characteristics—also the changing standards of equipment used, such as larger-sized cables having greater impedance angles, use of reactors of various values, complicate the problem and make it a continuous one.

These considerations make desirable the use of an alternating-current calculating table representing both resistance and reactance, though not to replace the direct-current table which, because of its simplicity of operation offers a quick and sufficiently accurate solution for most problems. Another valuable use of an alternating-current representation of this system could be obtained by designing the scheme to include units representing loads and their power factors for the purpose of determining the most economical arrangement of the transmission system for

1. The generator reactance which is active under sudden short circuit.

load distribution within the limitations of operation, short-circuit currents, etc.

O. R. Schurig: Both Mr. Doherty and Mr. Armbrust have referred in their discussions to the problem of determining experimentally, by miniature equivalent circuit, the division of normal current flow in a network. The following discussion is devoted to the question of determining whether this problem may be solved satisfactorily by a d-c. miniature system such as the "short-circuit calculating table." There are three reasons why a d-c. device is not to be recommended for general application to load-current division problems; viz:

- (1) For normal current flow in the lines of a network a higher degree of accuracy is generally required than for short-circuit currents.
- (2) Capacity currents frequently are a material portion of the total current flowing.
- (3) Tie-line current flowing between generating stations or between substation busses may be greatly in error, when determined by a d-c. method.

FIG 1—DIAGRAM OF CIRCUIT ILLUSTRATING DETERMINATION OF NORMAL CURRENT FLOW (DUE TO LOADS) IN A DISTRIBUTION NETWORK

Circuit at Z_A represents three cables in multiple with a current limiting reactor in each cable at the generator end.

Circuit at Z_B represents two cables in multiple with a current limiting reactor in each cable at the generator end.

The first point may be considered with reference to the accuracy data presented in the paper: If, for example, the power factors of the loads in a system range from 0.70 to 0.95, the corresponding range of impedance angles is from 46 deg. to 18 deg., and the load reactances in these two cases are 71 per cent and 31 per cent, respectively, of the load impedance magnitudes. Since the load currents depend on impedances, rather than reactances, it will be seen at once that the reactance method is entirely unsuitable under load conditions similar to those mentioned. Thus the impedance method, only, comes into consideration. Its accuracy for load current division will be considered below.

Capacity currents cannot be represented together with load currents in a d-c. miniature system, because of the wide phase difference between them. It follows, then, that for systems having large capacity charging currents—such as high-voltage aerial systems with long lines—the d-c. method applied to the determination of normal-current division cannot give representative results.

Interchange currents flowing over tie lines between generator

busses are frequently displaced in phase from the generator currents feeding these busses. Since a d-c. representation of these currents cannot take account of their respective phase relations, considerable errors in these interchange currents may be encountered if the d-c. method is applied.

Similarly, the currents flowing in tie lines between substation busses are likely to be greatly misrepresented by the d-c. method, when the power factors of the loads on these busses differ materially. This will be shown by the following example. Let the circuit be that of Fig. 1. The load currents I_{L1} and I_{L2} are given and will be considered fixed in magnitude and phase. The problem is to determine currents I_A , I_B , I_C , and I_G by the d-c. method employing impedance magnitudes. Let

$I_{L1} = 420$ amperes at power factor 1.0

$I_{L2} = 500$ amperes, lagging 41 deg. behind I_{L1} , (i. e. at power factor 0.75)

$Z_A = 0.307 + j 0.599 = 0.673 / 63$ deg. ohms.

$Z_B = 0.276 + j 0.485 = 0.558 / 60$ deg. ohms.

$Z_C = 0.246 + j 0.148 = 0.287 / 31$ deg. ohms.

NOTE: These line impedances are for 12-kv., 3-conductor, cables at 60 cycles per sec. The values of Z_A and Z_B include current limiting reactors.

The results are as follows, for the above fixed values of I_{L1} and I_{L2} .

Current symbols referring to Fig. 1	Correct currents determined by complete a-c. solution. Amp.	Currents by d-c. method employing impedance magnitudes. Amp.	Error of approximate currents
I_A	406	417	3% too high
I_B	459	503	10% too high
I_C	135	—3	98% too low
I_G	863	920	7% too high

It is seen that the currents over circuits A and B and in the generator are not over 10 per cent in error, while the tie-line current I_C is entirely misrepresented by the d-c. method. The large error is due to the phase displacement between load current I_{L1} and tie-line current I_C , the latter current being substantially "wattless." This example, therefore, illustrates how the d-c. method may grossly mislead in the determination of tie-line current for systems having loads of dissimilar power factors.

It should be pointed out here that in short-circuit current determinations with the calculating table the likelihood of excessive errors in tie-line currents is far more remote since there is only one load—i. e. the short-circuit—and since parallel lines of widely dissimilar impedance angles are generally avoided on account of the interchange currents they produce in normal operation.²

In a strictly radial system of distribution, i. e. with no tie lines between substations, the last-mentioned errors will not occur in a d-c. representation of the system. On the other hand, it may be argued that in the purely radial type of distribution system calculation of load current division is less complicated and the need for a miniature system less urgent than for systems having a complex distribution network.

To summarize: For the determination of normal current division in a-c. distribution networks, the d-c. miniature test method is not generally applicable on account of errors due to dissimilar load impedance angles (i. e. dissimilar load power factors) and to the neglect of capacity currents. Under these conditions, the solution of this problem by miniature test calls for an a-c. miniature system having reactors and resistors, and, in some cases, condensers. These conclusions corroborate those presented by Mr. Armbrust and by Mr. Doherty.

2. This particular cause of interchange currents in normal operation is largely eliminated by designing parallel distribution circuits to have equal impedance angles, i. e., to have substantially equal ratios of reactance to resistance. Equality of line impedance angles does not, however, do away with tie-line currents caused by the nature of the loads on a system.

Qualitative Analysis of Transmission Lines

BY H. GOODWIN, Jr.

Member, A. I. E. E.

Engineering Staff of Sanderson & Porter, New York, N. Y.

Review of Subject.—The process proposed in this paper is called "Qualitative Analysis of Transmission Lines" because of its similarity to chemical qualitative analysis.

Based upon a previous presentation by Mr. Percy H. Thomas the "critical load" for transmission lines is introduced with a simple formula for determining it and various rules are given for the variation of power factor voltage, etc., of a line by relating the actual load to the critical load.

The most important parts of Mr. Thomas's presentation are abstracted and presented showing the fundamental physical and mathematical basis for this method of analysis.

The detail development of the formula for the critical load is then given and the effect of the various line constants upon it are briefly discussed.

Working from the critical load a vector interpretation of the action of a long high-voltage transmission line is given. From this vector interpretation it is possible to predict certain essential operating characteristics of transmission lines.

Based on the previous generalities practical examples of transmission lines operating at critical load are then given showing how it is possible by the qualitative analysis to predict desired conditions of operation. Two of these examples show the operation of a 3100 mile copper transmission line of 220 kv. nominal potential. Another shows a 3875-mile aluminum transmission line.

In the conclusion an appeal is made for further work along these lines and it is pointed out particularly that this is not an approximate method but an exact method for "Qualitative Analysis of Transmission Lines."

INTRODUCTION

THIS paper is entitled "Qualitative Analysis of Transmission Lines" because of the similarity of the process set forth to *qualitative* analysis in chemistry. Transmission line calculations according to the well-known formulas can be considered as in the class of *quantitative* chemical analysis; results are obtained not only giving the character of the quantities but also their amounts.

The value of *qualitative* analysis of transmission lines lies first in the results obtainable by the simple rules set forth. But it has a second and greater value to one trying to arrive at a conception of what is really happening in a transmission line; it gives a basis for a mental picture and a true conception of the evolutions in the line and the effects upon them of changes in any of the constants.

CRITICAL LOAD

The qualitative analysis proposed is based upon the fact that for each transmission line there is a *critical load* which at unity power factor behaves practically like direct current on the line.

Analyses are made by relating the load conditions for a given line to this critical load.

The critical load was first discovered and presented to the Institute by Mr. Percy H. Thomas in 1909¹. Unfortunately little practical use has been made of Mr. Thomas's discovery. The physical concept behind the critical load formula can not be better given than in Mr. Thomas's own words which will be quoted later.

Starting from Mr. Thomas's conclusions, the formula for the critical load of any transmission line has been derived and is as follows:

$$kv-a. = \frac{10^3 (kv.)^2}{\sqrt{L/C}} \quad (1)$$

For commercial lines this can be expressed with accuracy within 5 per cent:

$$kv-a. = \frac{(kv.)^2}{0.4} \quad (2)$$

$$or: kv-a. = 2.5 (kv.)^2$$

If the "Y" voltage is used the result is kv-a. per phase. If the delta voltage is used the result is total kv-a.

For a few voltages within the ordinary commercial range the critical loads are as follows:

Volts	Critical Kv-a.
200,000	100,000
141,000	50,000
100,000	25,000
60,000	9,000
20,000	1,000
10,000	250

Some of the properties of the critical load which are useful in analysis of transmission lines of present commercial lengths are as follows:

(1) The critical load when placed on a transmission line at unity power factor will be transmitted at unity power factor. The current will be constant throughout the line. The voltage drop will be the same as for direct current (IR). The power loss will be equal to the direct-current power loss (I^2R).

(2) If the kv-a. load is greater than the critical load, the power factor at the sending end of the line will be always more lagging than the power factor at the receiving end of the line.

(3) If the kv-a. load is less than the critical load, the power factor at the sending end of the line will always be more leading than the power factor at the receiving end of the line.

(4) If the load is the critical kv-a. but at a leading power factor, the power factor at the sending end of the line will be still leading but nearer unity.

(5) If the load is the critical kv-a. but at a lagging power factor, the power factor at the sending end will still be lagging but nearer unity.

1. "Output and Regulation in Long Distance Lines"; Percy H. Thomas, TRANSACTIONS, A. I. E. E. 1909.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 14-17, 1923.

If the line is longer than any line now in commercial service either leading or lagging critical loads should finally reach the stable condition at a very slight leading power factor, usually better than 0.995.

For a line of unusually large diameter at a small spacing or unusually small diameter at a large spacing the value of $\sqrt{L/C}$ should be taken from Fig. 1 and used in formula (1). The accuracy of formula (2) is however within 5 per cent plus or minus for present commercial transmission systems.

The values of the critical kv-a. with various voltages may easily be read from the slide rule by setting it as shown in Fig. 2. Set "4" on scale *B* opposite "1" on scale *A*. The rider is set to the voltage on scale *C* and the critical load read on Scale *A*. The decimal point can best be determined by remembering that the critical load for 100 kv. is 25,000 kv-a.

QUOTATIONS FROM "OUTPUT AND REGULATION IN LONG DISTANCE LINES," BY PERCY H. THOMAS

As stated above the physical conception and fundamental mathematics of the critical load of a transmission line were presented by Mr. Thomas in 1909. Nothing better can be said than what he wrote at that time. The more important parts of his presentation are as follows:

"Electrical Action in the Line. The critical electrical feature of a transmission system is the action of the line itself. In the passing of energy over a line there is, first, the loss of energy in practical overhead work represented only by the resistance losses. But with power passing over a line at high voltage, a certain amount of leading energy flows to charge the line capacity. This energy in its travel causes a tendency for the potential to rise along the line in the direction of the flow of the leading energy. Similarly there flows to the line a quantity of lagging energy, by virtue of the inductance of the line and the flow of current therein. This lagging energy tends to cause a drop of potential in the line in the direction of its flow. The resultant effect is the difference of the leading and lagging energy-flow, superimposed, of course, upon the true power transmitted and the resistance-drop. *****

"When the lagging energy predominates over the leading energy, the tendency is for a drop in potential along the line in the direction of the lagging flow—the well known inductive drop, which is combined with the ohmic drop.

"When the leading energy predominates there is a tendency for a rise of potential in the direction of the leading energy-flow, which must be combined with the ohmic drop as before. The rise of potential effect of the leading energy will be opposed to the ohmic drop when the transmission of power and the flow of leading energy are in the same direction. * * * * *

"Now consider the case when the leading and the lagging energies are equal and when they are opposite in phase; that is, when the load power factor = 1.

In this case there will evidently be no appearance in the line of demand on the generator for either lagging or leading energy, and no tendency either for a rise or a drop of voltage therefrom, and the ohmic drop is the only loss of voltage. This condition will be actually realized in practise if the leading and lagging energies of the line are equal and with a load of unity power factor. If, however, the load current has a lag or a lead, the leading and lagging energies, while they may be equal, will not be opposite in phase and will not neutralize each other. The rather remarkable conclusion follows—that in this case of complete neutralization the loss of voltage is only the ohmic drop and is independent of frequency and is of the same value as with the direct current. Thus if this condition can be realized, and there enters no secondary effect, there will be no further economy in direct-current transmission as far as energy loss or voltage line drop is concerned, the same effective line voltage being used. But the difficulty is that this condition of equality of the leading and the lagging energy in the line is usually not met with in practical transmission of relatively short length and often cannot be economically obtained.

"The unfortunate condition exists that the leading energy, being the condenser energy, is practically constant, whatever the load on the line, since it depends only on the voltage of the line. On the other hand, the lagging energy depends only on the actual amount of power or current being transmitted, since it varies as the square of the line current. Thus with half load or no load, a line that was balanced for full load would have a large excess leading energy flow.

* * * * *

"It should be carefully borne in mind that the leading and lagging energy and energy-loss so far discussed are wholly confined to the line and have no necessary relation to the leading or lagging current in the load.

"The factors by which the relative values of the leading and the lagging energy of the line are controlled are: the line voltage, the actual load or current, and the ratio of the line inductance and capacity per unit length. The energy taken by the capacity of the line varies as the square of the line voltage, so that this factor is of extreme importance. The lagging energy of the load varies as the square of the current, as has already been mentioned. Neutralization of the leading and lagging line energies can be obtained only when the power factor of the load current is unity, for only then the leading and lagging energies are opposite in phase.

"The current of the line, of course, decreases directly with the increase of line voltage chosen, if the power transmitted be kept constant.

"The energy flowing to the capacity of the line per unit length is proportional to pCV^2 , where pC is the capacity susceptance and V the voltage. The lagging energy will be proportional to pLI^2 , where pL is the inductive ohms and I the current. If these are equal

then $V/I = \sqrt{L/C}$, which is the condition of balanced out-of-phase energy. It is clear that this can be reached for any line and voltage by properly choosing the current, and for any current by properly choosing the voltage. It is also clear that the condition is independent of frequency.

"Equation (34) of the companion paper gives the line voltage equation when $R = 0$. Here if the current or voltage is chosen to fulfill the above condition . . . the voltage of the line is constant as it should be. The resistance is chosen as zero, as otherwise the change of voltage along the line will destroy the exact balance of the leading and the lagging energy.

"Thus as the net result, the ratio of the leading to the lagging energy varies as the fourth power of the voltage when the power transmitted remains the same. The capacity of the line can be increased by adding condensers in parallel across the line at regular and sufficiently frequent intervals; the inductance can similarly be increased by the addition of choke coils in the same manner. But these expedients have never found much favor. As the power and voltage are often fixed by the other considerations, some other method of altering this ratio than change of power or voltage would be desirable. * * * * *

"It should be said that in this matter of adjustment of the leading and lagging line energies, a change of frequency is of no avail, since both elements, capacity and inductance, are affected in the same manner. Furthermore, while a certain voltage may be most favorable in some particular case for balancing the line effects and reducing the line-drop to the ohmic equivalent, it does not necessarily follow that this voltage will give the best transmission condition, for the advantage of a higher voltage may easily more than offset the favorable adjustment of the leading and lagging energy of the line. Furthermore, the most favorable line conditions will not always be the most favorable for other parts of the system and any complete design will be a compromise, as usual. * * * *

"In the main the electrical action of the line has now been briefly outlined. The most notable features are:

"1. That by properly balancing the leading or capacity energy and the lagging or inductive energy in the *line itself*, the full-load transmission will be as though the line had only ohmic resistance.

"2. That a reasonable constancy of voltage conditions on the line *for all loads* may be obtained by supplying the leading energy in the condition when the load is off or light, partly or wholly from the receiving end. * * * * *

SUMMARY

"The more important definite conclusions arrived at may be summarized as follows:

"1. To obtain the most economical transmission of power over a long-distance line, it is necessary to have

balanced the leading and lagging energies of the line itself, and at the same time to have unity power factor in which case the transmission is similar to direct-current both as to voltage drop and energy loss.

"2. The power-factor at the load end may be made unity or otherwise controlled by synchronous machines, generators or motors, located at the receiving end of the line.

"3. To obtain satisfactory regulation for high-power long-distance transmission, the leading current taken by the line at light loads should be fed mainly from the receiving end. By this means the voltage rise from the receiving end; that is, the drop from the power house to the receiving end, can be kept nearly constant for all loads. Adjustment of the line-drop can be accomplished at any load by varying the amounts of the leading energy or charging current supplied to the respective ends of the line.

"4. The voltage regulation and line losses may be controlled for any commercial frequency and for any percentage load condition—as far as its electrical action is concerned—using a conductor of sufficient section, by making the leading and lagging line-energies equal at full load, and by feeding suitable proportions of the charging current at other loads from the respective ends of the line, the greater portion being from the receiving end.

"5. The adjustment of the leading and lagging energies taken by the line itself may be accomplished by the choice of voltage and load, or by adjusting the ratio of the capacity and inductance of the line. . . .

"6. Calculations of these long high-voltage, high-power lines may be made approximately only by formulas founded on the assumption of localized capacity. The error in the voltage may be several per cent. The approximate formulas are especially unreliable when the leading and lagging energy in the line are equal.

* * * *

"9. While it is possible by a cut-and-try method for any given case to arrive at the best conditions of capacity, resistance, inductance, and the power-factor at the load end of the line, yet, the best results will be obtained most directly by planning the line in accordance with the principles here explained.

"While comparatively few high-tension power-transmitting systems now installed are of sufficient magnitude to require as careful a treatment as that outlined here, the development of this art cannot proceed much further without some such method. It is the hope of the writer that here, either directly or, perhaps more likely, by suggestion, he has somewhat forwarded this development."

EVOLUTION OF FORMULA FOR CRITICAL LOAD

Mr. Thomas, as quoted above, gives the fundamental relation for the critical load: $V/I = \sqrt{L/C}$. This

can be converted into the more convenient form given in the earlier part of this paper as follows:

Let kv-a. = total kv-a.

$(kv-a.)_p$ = kv-a. per phase

E = delta voltage in kv.

$e = \frac{V}{1000} = Y$ voltage in kv.

I = current per phase

Then kv-a. = $3 (kv-a.)_p$

$e I = (kv-a.)_p$

$I = \frac{(kv-a.)_p}{e}$

Substituting:

$$V/I = \frac{1000 e}{I} = \frac{1000 e}{\frac{(kv-a.)_p}{e}} = \frac{1000 e^2}{(kv-a.)_p} = \sqrt{L/C}$$

$$\therefore (kv-a.)_p = \frac{1000 e^2}{\sqrt{L/C}} \quad (3)$$

$$\text{and kv-a.} = \frac{1000 E^2}{\sqrt{L/C}} \quad (4)$$

These last two equations, (3) and (4), are of exactly the same form. The difference in notation shows that

FIG. 1—CONDUCTORS IN ONE PLANE

S' = Distance between conductors in feet; D' = Conductor diameter in inches. For conductors in triangular arrangement: divide $\frac{S'}{D'}$ by 1.26

and use result, $\sqrt{\frac{L}{C}}$ for all sizes and spacings of aerial high-tension lines.

if the Y voltage is used the result is the critical kv-a. per phase, while if the delta voltage is used the result is the total kv-a.

By applying practical values of conductor size and spacing to Fig. 1 it is found that $\sqrt{L/C} = 400$ is a fair average value. Substituting this value in equation (4) gives:

$$kv-a. = \frac{1000 E^2}{400}$$

$$kv-a. = \frac{E^2}{0.4} \quad (5)$$

in which E is expressed in kilovolts.

DISCUSSION OF CRITICAL LOAD FORMULA

Equation (4) for the critical load may be rewritten:

$$kv-a. = 1000 E^2 \sqrt{C/L} \quad (6)$$

In this form it shows plainly that an increase in the capacitance of the transmission line will increase the critical load; a decrease in capacitance will decrease the critical load. In contrast to this, an increase in the reactance of a line will decrease the critical load and a

FIG. 2

decrease in the reactance will increase the critical load. Since the capacitance and reactance of transmission lines fundamentally bear a reciprocal relation it is seen that any change in size or arrangement of conductors will affect the reactance and inductance inversely. This will change the value of the quantity under the root sign by the square of the factor of change. But since this is under the root sign it will only affect the kv-a. directly as the change in either one of the quantities. For instance if it were possible to increase the capacitance of a circuit 50 per cent and therefore decrease the inductance a similar amount the critical load would only be increased 50 per cent.

For very high-voltage lines the full loads will correspond quite closely to the critical loads. However light loads will depart very far from the critical loads and those experienced with such lines know that light load conditions often present greater problems than full load. Looking at equation (6) to determine what is necessary for light loads, it is seen that the critical load may be reduced by decreasing the capacitance of the line or by increasing the inductance. To decrease the capacitance of the line is a difficult thing, but remembering the derivation of the equation it is easy to see that the same result may be produced by reducing or neutralizing the charging current. This can be done by connecting reactance coils across the circuit at various points or by the use of synchronous phase-modifiers operated under-excited so as to draw a lagging current from the line. This second has the advantage that under full-load conditions the phase-modifiers could be over-excited to draw a leading current and so increase the critical load. These devices need not be uniformly distributed but can be lumped at different points as determined for each line. As a matter of fact

any line so long as to require modifying devices at other than the receiving end would probably have several distributing substations at which could be located the necessary modifying devices for proper operation at light-load, and increasing the critical load for full-load conditions. The decrease of the critical load for light load operation by increasing the inductance presents practical difficulties so that it will probably not be used for power transmission. This is the "loading coil" method used on telephone circuits where it is highly practical and the methods of decreasing the equivalent capacitance are impractical.

VECTOR INTERPRETATION OF CRITICAL LOAD TRANSMISSION

The best conception of what is happening in a transmission line carrying its critical load at unity power

FIG. 3

factor can be obtained by following Mr. Thomas's suggestion of assuming $R = 0$. Mr. Thomas points out that under these conditions the effective values of current and voltage will be constant throughout the length of the line. In addition to this it should be noted that the vector position will change throughout the line. Starting from the receiving end with the current and voltage in phase and traveling toward the sending end the vectors will advance in a counter-clockwise direction (Fig. 3). At the end of a quarter wave-length both current and voltage vectors will be 90 degrees ahead of the vectors at the receiving end. At one-half wave-length the vectors will have advanced 180 degrees and will be in exact opposition to those at the receiving end. Continuing, at the end of one wave-length the vectors will be in phase with those at the receiving end but one revolution in advance. This can be continued indefinitely. Since electricity travels with the speed of light the wave-length for 60 cycles is 3100 miles and a quarter wave-length is 775 miles. Since the voltage and current are in phase at each point, full power is transmitted throughout. Resistance is then the only impediment to long distance transmission of alternating current electrical energy.

It is therefore necessary to investigate the effect of resistance on the transmission of the critical load. Mr. Thomas has pointed out that the voltage drop with the critical load at unity power factor will be IR . That is, the increase in voltage from the receiving end toward

the sending end is directly proportional to the resistance involved. The critical load being proportional to the square of the voltage, it will increase at a rate dependent on the square of the resistance (R^2). The actual load is increasing by the line losses which are $I^2 R$ involving only the first power of R . This means the actual load is not keeping pace with the critical load and there must therefore be a change in phase relation of the current and voltage.

Going back to Mr. Thomas's fundamental conception, this disproportionate rise in voltage causes a flow of leading energy too great to be balanced by the lagging energy of the load current. This then must exhibit itself by a leading component of the current.

Fig. 4 shows the condition. I_L is the load current. I_c is the capacity current due to the increase of voltage above that corresponding to the actual load. I_R is the resultant current causing the power loss and voltage drop in the line. This resultant current enters as the square and since it is larger than I_L in some measure offsets the R^2 effecting increase in voltage, but the effect is very slight.

The leading current I_R has another effect and that is to decrease the voltage drop according to the familiar effect of a leading current flowing through inductance. These two actions will continue until the losses are at too rapid a rate for the slowly increasing potential. The action will then reverse and the current swing back in phase until the voltage is again sufficient to maintain the load and losses. The power factor would then again be near unity and the oscillation to leading would recur. This swinging of phase angle would continue until it finally settled at some value of advance which is very small, amounting only to from 2 to 6 degrees (power factor of 0.9994 to 0.9945) for commercial lines.

FIGS. 4 AND 5

It should be borne in mind that the relative conditions just described refer to the relation at different points along the line and not to varying conditions at one point. With the load constant the conditions at any point will be constant. But the phase relations will oscillate as different points along the line are considered.

The ideas presented in the previous paragraphs and some other conceptions can probably better be grasped by comparison with the familiar vector diagram of a current flowing through a lumped resistance and reactance without appreciable capacitance. In Fig. 5 E_r and I_r indicate the voltage and current at the

receiving end. E_r and I_r indicate the voltage and current at the sending end. It is to be noted that I_s and I_r are equal and in phase. E_r and E_s are connected by the impedance triangle of the reactance. The power factor is unity at the receiving end and lagging at the sending end.

Fig. 6 shows a similar diagram for a transmission line having distributed inductance and capacity with the critical load at unity power factor. The effect of the distributed inductance and capacity is to curve the sides of the impedance triangle and reduce the difference between E_r and E_s to an amount equal to

FIGS. 6 AND 7

$I R$. From the discussion in the first part of this section it is evident that I_s would lead E_s by an angle too small to be shown on the diagram.

Proceeding from Fig. 6 it is interesting to consider the conditions which might produce zero voltage drop in the line. It would appear that if I_r were advanced by a small angle equal to the small angle of the impedance triangle of the line that this might be accomplished. Advancing I_r would swing the impedance triangle about its lower corner so that E_s would be thrown in to the circle which has a radius of E_r . Fig. 7 shows the resultant conditions. The result of calculations given later show this to be true for two transmission lines of present commercial length.

PRACTICAL EXAMPLES OF TRANSMISSION LINES
OPERATING AT CRITICAL LOAD

Many of the generalities discussed in the preceding sections of this paper can be much better appreciated by a few practical calculations. The results of some of these will therefore here be given.

All of these calculations have been made by the use of the rigid hyperbolic formula and are of a high order of accuracy. A true sine wave has been assumed. The conductors have been considered as placed in one plane with sufficient transpositions to make them symmetrical.

Critical Load for Practical Lines:—In order to show the relation of the critical load to various lines now in service Table I has been prepared for a few lines of

then indicate that by designing a line properly in relation to its critical load it is now possible to transmit at any commercial frequency many times as far it would be commercially practical to do so.

It must be noted particularly that the results in this table are for full load only and are not set forth to show the operation of a line with variable load. With such a line as this it would be necessary from a financial point of view to keep the line operating at 100 per cent load factor so that light load conditions need not be considered. It would be necessary to consider how to get such a line into service, but this could be accomplished in a number of ways if the line were otherwise commercially feasible.

Table V shows a line in every way similar to that in Table IV except that the load power factor is slightly more leading, being the same as Table II for flat voltage. Table V shows that with this longer line there is practically no difference in the voltage drop. The effect of flat voltage on the first 200 miles of the line is made up by the greater drop in the remainder of the line. Table V does show the variation of the angle from side to side of the stable angle of 2.02 degrees as used in Table IV.

To visualize the results of Tables IV and V better they have been plotted in Fig. 8. Near the top the vector position at five points on the line is given showing plainly the complete revolution through the length. Yet, at each point the current and voltage are practically in phase. The voltage, current and load rise almost uniformly from the sending end to the

receiving end. The power factor curves show the uniform power factor predicted and calculated in Table IV, and the oscillating power factor of Table V gradually

FIG. 8—OPERATING CHARACTERISTICS OF VERY LONG COPPER TRANSMISSION LINE

approaching the uniform value of Table IV. The very large scale used for the power factor should be appreciated for the variation is really very slight.

*d = leading; g = lagging.

Characteristics of Very Long Aluminum Line: The line drop and losses were so low for the copper line that an extra long aluminum line has been calculated to reach more quickly the conditions that might obtain with a copper line 10,000 or 15,000 miles long. Table VI shows the operating characteristics of this very long aluminum transmission line. This is in every way similar to Table V except that the length has been extended to a total of 3875, being $1\frac{1}{4}$ wave-lengths. The conditions were not chosen for constant power-factor but so that "Point 4" with 200,000 volts would correspond to "Point 1" of the copper line in Table V, and the aluminum line in Table III for "predicted flat voltage." This again shows that the flat voltage condition cannot be extended for a great length of line due to the power losses; the effort to do this just causes a swinging of the power factor. The decrease of swing of the power factor as the sending end is approached is evident; the angle for stable operation is 6.06 degrees.

CONCLUSION

The formula for the critical load and various rules for its use were set forth at the beginning of the paper and therefore will not be repeated here.

It is undoubtedly possible that the form of expression of the rules can be improved and considerably extended. It is therefore hoped that this paper will not only lead many to a better conception of what is going on in a high-tension transmission line, but will also lead them to develop and present their thoughts so that others may have the benefit of a further practical understanding of the nature of transmission of electrical energy.

Included in the paper are examples of very long transmission lines to show how their action may be predicted, rather than as examples of economical lines for any particular condition.

It must be remembered that while approximate results can be obtained in some cases that the formulas are *not* approximate formulas but for the purpose of obtaining quickly in advance of accurate calculations a "Qualitative Analysis of Transmission Lines."

Discussion

R. D. Evans: In discussing Mr. Goodwin's paper, we wish to comment on three points, as follows: 1. The conditions for the most efficient transmission of power; 2. Stable operating conditions for long transmission lines; 3. The desirability of the circle diagram for calculating performance of transmission lines.

The first statement given under the caption of "Summary," suggests that the transmission of the critical load will be most efficient at unity power factor at the receiver. We wish to point out, however, that the most efficient transmission of power for a given transmission line and receiver voltage occurs at a slightly lagging power factor. This condition can best be explained by means of the circle diagram.

In Fig. 1, is shown a circle diagram for a transmission line, 125 miles in length. In this diagram, the receiver load is plotted in kw. along the X axis and in reactive kv-a. along the Y axis.

The circle with solid line, with radius C_R is a graph of the different receiver load conditions which satisfy certain definite voltage conditions at the supply and receiver ends of the transmission line. The dotted circle represents a similar graph for a different supply voltage condition. The transmission losses for a definite transmission line and with constant receiver voltage may be represented by a series of concentric circles, only segments of which are plotted. It will be noted from the loss circles, that the line lm represents the receiver load and supply voltage conditions for minimum transmission loss or maximum transmission efficiency for the particular amount of power to be transmitted. The critical load for the transmission line, is indicated graphically as a load at the point x . It will be observed, that lower transmission line losses will occur if the critical load is operated at a slightly lagging power factor and at a slightly higher generator voltage. As indicated by the condition for the point y , most

FIG. 1

transmission line loads are of lagging power factor and synchronous condensers are required to improve the power factor and thus, regulate the system voltage. Hence, operation of a transmission line at the critical load, as indicated by the point x of Fig. 1, will occasion greater transmission losses, higher condenser losses and require greater condenser capacity than would occur under the more favorable operating condition indicated by the point y .

The second point we wish to discuss is in reference to stable operating conditions of transmission lines. In Mr. Goodwin's paper, there is included under the heading of "Practical Examples of Transmission Lines Operating at Critical Load," a list of existing lines with their critical loads; also some data as to very long transmission lines. By inference, it might be supposed that it is practicable to transmit over 100,000 kw. at 60 cycles over a distance of 775 miles. The circle diagram for this very long transmission line, given in Table No. 4 of Mr. Goodwin's paper, will appear as indicated in Fig. 2. The critical load occurs at the point x and it will be noted that the transmis-

sion system will not deliver any appreciable load in excess of the critical load. If this line supplied synchronous machinery at the receiver, the operation would be unstable and difficulty would be experienced in maintaining synchronism. Furthermore, with the actual, transformers would be required which would further limit the amount of power that might be transmitted with satisfactory operating conditions. The circle diagram also shows that, in order to maintain the same voltage at no load as at full load, the reactive kv-a. required would be very nearly equal to the maximum kv-a. that might be transmitted over the transmission line. With a 60-cycle line of 775 miles in length, there would be a very real problem in limiting transmission line voltages, in case the load were dropped for any reason and the problem of making the generators non-self-exciting would be extremely difficult. Mr. Goodwin has pointed out that there would be difficulties incident to the operation of these very long transmission lines at light loads, but the speaker wishes to emphasize that the full-load operating condition would also be unsatisfactory. On such long transmission lines in order to insure stable operating conditions, loaded transmission lines with intermediate synchronous condenser stations should be employed.

The speaker feels that there is danger in the idea which has been advanced in some quarters that it is possible with unloaded transmission lines to transmit very large amounts of power per

FIG. 2

circuit to almost unlimited distances and that all that is necessary is to build a 220-kv. line and close the switches and the system will operate satisfactorily. The problem, however, is not as simple as that although it may be solved readily enough. There are factors such as unstable operating conditions that must be given consideration because of the large amount of power which may be involved and which may require loading of the transmission lines.

In connection with studies of transmission line performance, it seems desirable to emphasize the advantages resulting from the use of the circle diagram method of solution. This method was rather fully discussed in articles by H. K. Sels and the speaker, published in the *Electric Journal*, during 1921-1922. The advantages of this method arise from the graphical presentation of the different voltage, load, and transmission loss conditions. This method readily shows the conditions for maximum efficiency on the transmission system for different conditions of supply and receiver voltages. The diagram also gives directly, information as to the probable stable operation of the transmission system. It is to be emphasized that a mathematical solution of a transmission line may not be a stable operating condition.

Summarizing, the maximum efficiency of a transmission line does not occur for the critical load at unity power factor, but at a slightly lagging power factor. Second, critical load conditions on very long transmission lines will have unstable operating characteristics, which may be avoided in a practical way, only by the use of loaded transmission lines with intermediate condenser stations. Third, the circle diagram method of calculating transmission lines has many desirable characteristics, including a graphical presentation of the various conditions with regard to variation in generator and receiver voltages, maximum transmission efficiency, and stable operating characteristics.

V. Karapetoff: I should like to discuss the first page of Mr. Goodwin's paper, particularly the statements regarding the properties of the critical load. Mr. Goodwin refers to Mr. Percy H. Thomas's paper of 1909, and so I looked up that paper for a confirmation or a proof, of the statement made here, but I found none. I looked up Mr. Thomas' companion paper, his mathematical discussion of the same date, but there also I could find no proof, and so I tried to check these statements mathematically. They do not seem to check, and I feel that Mr. Goodwin owes us an appendix to the paper, proving the statements made on the first page.

The general equations of a transmission line are quoted on p. 135 of my paper on the "Heavisidion," and I shall only refer to them without repeating them here. Mr. Goodwin's critical load is one for which $E_2 = Z_0 I_2$, so that the second term in my eqs. (1) and (2) is equal to zero. Thus, the critical load is characterized not only by the voltage and the current, but also by a definite phase angle which depends on the line constants.

In the light of this theory, I should like to quote some of Mr. Goodwin's statements: "The critical load when placed on a transmission line at unity power factor will be transmitted at unity power factor." While I realize that the phase angle of the surge impedance may be small, nevertheless, I feel that in a statement of this kind, it should be explained that this only is so provided that the resistance and the leakage are neglected. I am afraid that the above statement may later be used and quoted as a reference, and the fact that it is only approximate may not be noted.

The second part of the statement reads: "The current will be constant throughout the line." This is not quite true, because both the current and the voltage have a decremental factor, αS . Again, neglecting the resistance and the leakage, the foregoing statement is true, but this limitation must be definitely stated.

The second statement is as follows: "If the kv-a. load is greater than the critical load, the power factor at the sending end of the line will be *always* more lagging than the power factor at the receiving end of the line." We cannot compare the critical load with any other load unless we take into account the power factor. Such a general statement does not seem to be true without further qualifications. Moreover, the power factor varies from leading to lagging and back, as you proceed along the line. If you start with a receiver condition, you can assume the generator end to be anywhere you please, one mile, seven hundred miles, or fifteen hundred miles, from the receiver end. There is no definite generating end in that sense, and as you proceed from the receiver end, you will meet line conditions of both leading and lagging power factor; thus, the above statement, as you may see, depends on where you take the generating end.

For all these reasons, I feel that Mr. Goodwin owes us much more explanation and proof than he has given us.

C. P. Steinmetz: A transmission line has four constants, two representing the energy dissipation, and two the energy storage, as depending on current and on voltage respectively.

1. The resistance r , calculated in the usual manner from material and size of wire, represents the *energy dissipation* depending on the line current: $r i^2$.

tion occurs, the main wave and the reflected wave superimpose, and in the resultant wave the voltage is the sum and the current the difference of the component waves (or inversely), and for the resultant waves, this simple relation between voltage and current does not hold any more. That is, in the study of circuit protection, the effect of reflection (and refraction) and the voltage rise possible thereby, must be separately studied.

An interesting application of the conception of the surge impedance r_0 is given in the paper.

The standard equations of the transmission line consist of two components; each of the current components equals the corresponding voltage component divided by r_0 , and in each of the components the voltage current ratio thus is constant and the phase relation between current and voltage constant, that is, the power factor constant. However, in the voltage the two components are added, in the current subtracted (or inversely), so that in the resultant wave phase relation, power factor and voltage current ratio along the line change. The first component decreases, the second one increases with increasing distance from the power supply. The latter therefore is the reflected wave. If then in the load at the receiving end the current is chosen so that r_0 is the voltage current ratio, then the second component wave vanishes, there being no reflection at the end of the line, as discussed above. This is the "critical load" referred to in Mr. Goodwin's paper.

Thus, the "critical load" of Mr. Goodwin's paper is given by: Volts divided by amperes equals surge resistance, where the surge resistance is given by equation (9).

A table of surge resistances for different sizes of transmission conductors are given in the following, for different distances between the conductor and the return conductor, and for different resistances between the conductor and the ground. The latter is the surge resistance which comes into consideration in discharges to ground, such as lightning. These latter values are approximate only, as they depend on the conductivity of the ground. The assumption has been made that the neutral plane lies 15 feet below the ground surface.

As seen, with very wide variations of conductor sizes and distance of the return conductor, the surge resistance varies relatively little, within the range of commercial transmission line proportions, so that for approximate estimate of discharge rates, etc., we may assume 360 ohms as the surge impedance of a line conductor against another line conductor, and 500 ohms as the surge impedance of a line conductor against ground.

TABLE OF SURGE IMPEDANCE
 $z_0 = 138.15 L/R$ ohms per conductor

~ 360 ohms. ~ 500 ohms

1. Assuming neutral plane 15 ft. below ground.

C. L. Fortescue: Mr. Goodwin's paper suggests to my mind old thoughts expressed in a new way. In this world we seldom get something for nothing, and this applies with particular truth to power transmission. In fact, a transmission line, like all electro-magnetic apparatus, requires for successful operation reactive power. As a matter of fact, reactive power on a transmission line is something like taxes—you cannot get away from it.

An engineer may elect to supply this reactive power entirely from the generator end, but his object is to transmit power from a locality where it is cheap to one where it is dear and to do this as expeditiously as possible.

To deliver real power requires a prime mover in addition to a generator, but reactive power does not require a prime mover, but it may be done by that wonderful machine called the synchronous condenser, which we may conveniently call a wattless power generator.

To transmit this wattless power is an expensive process, and we have to pay for it not only in the wattless power which we transmit to the point where it is required, but we have to produce more wattless power in order to transmit that amount. So that it is a very expensive process to transmit that power over a whole transmission line to the point where it is required. However, we can elect to transmit our wattless power or supply it at any point in the line where we please.

Suppose we have a transmission line of a certain length; our first idea is to transmit our power and supply also the wattless power required from the generator. To supply the real power, of course, we must have a prime mover, but the wattless power does not require a prime mover. We can use a synchronous condenser.

We may divide the line into sections and supply the wattless power to these sections by means of a synchronous condenser. They have to transmit the wattless power for the section in which they are placed a short distance only. This arrangement is absolutely necessary, so that we can supply the necessary wattless current at the least possible cost, and in so doing we do not gum up our power transmission, by transmitting this wattless current over the line. Therefore, the supplying of this wattless energy at the point where it is needed, not only gives us a better operating system, and a more stable transmission line, but gives us more economical power transmission for the same amount of wattless generating apparatus; in other words, with the proper use of synchronous condensers, we can transmit more power over a given distance.

Mr. Goodwin has treated the only case where the wattless power is applied at each point just as it is needed, through the medium of the distributed capacitance of the line that is the critical load condition, but for a practical operating line, we have to supply the necessary wattless power under all conditions of load, and the synchronous condenser enables us to do that because it can supply either condensive energy or inductive energy, according to the excitation.

As an actual fact, the total amount of condenser capacity required for a line so supplied with its wattless energy is much less for a given amount of power transmitted than one supplied at one end only. The economical spacing of the condenser depends on the cost of condensers, on the cost of substations, maintenance, etc. The idea that power can be transmitted without supplying the necessary magnetic energy which seems to be rather prevalent among some engineers does not hold.

There is another point which I wish to emphasize which Mr. Evans has brought out, and that is that the mathematical solution of the transmission line is not necessarily a practical solution. The peculiarities of the apparatus used for regulating the line, have to be considered as for instance, not only the synchronous condenser, but also the voltage regulators. Under certain conditions of load the system becomes unstable and is no longer operable.

F. G. Baum: I am glad to see engineers take up the matter of the constant potential transmission line. This type of transmission must finally come to be our standard for large power transmission because we must have (1) a safe and stable transmission, (2) a reversible transmission, and these can be had only with (3) a constant potential transmission system. But with a constant potential transmission the calculations become extremely simple because the charging current per unit length of

and having an indeterminate proportion of reactive kv-a. has been taken. No data are given in the paper to indicate how the amount of reactive kv-a. required has been determined, so it was probably determined by a trial and error process. In this way Mr. Goodwin has determined approximately the load for uniform power factor along the line. The exact formulas for this load will now be developed using the hyperbolic theory.

Let:

E_A, I_A, P_A = the voltage, current and volt-amperes, respectively, at the point A, the sending end of the line, expressed in vector form. Similarly for any point on the line, P, and for the receiving end, B.

z_0 = the "surge impedance" of the line.

$\alpha = \alpha' + j\alpha''$ = the "hyperbolic angle" per mile of line.

r, l, g, c = the resistance, inductance, leakance, and capacitance, respectively, per mile of line.

x = the distance from A to the point P.

The formulas for z_0 and α are as follows:

$$z_0 = \sqrt{\frac{r + j l \omega}{g + j c \omega}}$$

$$\alpha = \sqrt{(r + j l \omega)(g + j c \omega)}$$

If we consider a load having an equivalent impedance equal to the surge impedance of the line, connected at the receiving end, we have what Dr. Kennelly has named the virtually infinite line.³ That is to say, the line behaves as if it were infinite in extent. Dr. Kennelly has considered this line, and the formulas for this case are as follows:

$$E_P = E_A e^{-\alpha x} = E_A e^{-\alpha' x - j\alpha'' x}$$

where e is the base of natural logarithms.

$$I_P = I_A e^{-\alpha x} = I_A e^{-\alpha' x - j\alpha'' x}$$

$$P_P = P_A e^{-2\alpha x}$$

From these formulas, it is seen that the magnitudes of the voltage and of the current fall off from A toward B according to a simple exponential law. Also the angle between the voltages at any two points varies directly as the distance between them. The same holds true with respect to the currents. Furthermore, the volt-amperes fall off at double the rate of the current and the voltage, but still in accordance with an exponential law, and the power factor is constant over the whole line. It is apparently this load that Mr. Goodwin was searching for and he has hit upon a close approximation for ordinary commercial transmission lines. In fact, when $r = 0$ and $g = 0$, z_0 becomes equal to $\sqrt{L/C}$.

The formulas for the virtually infinite line are very readily adaptable for use with ordinary logarithmic tables. As already pointed out, the change in angle is directly proportional to the change in distance. The length corresponding to an angle of 360 deg. is the wave length of the line and is equal to

$$\frac{2\pi}{\alpha_2} \quad \text{The angle corresponding to any other length is found by}$$

direct proportion from this value. For the transmission line given in Table IV, the wave length is 3043.9 miles (4898.5 km.). The wave length of a line containing resistance depends not only on the frequency but also on the relative values of resistance, inductance and capacitance.

In order to determine the magnitude of the voltage at any point, the formula is $E_P = E_A e^{-\alpha_1 x}$. This may be transformed as follows:

$$\log_e E_P = \log_e E_A - \alpha_1 x$$

$$\log_{10} E_P = \log_{10} E_A - 0.43429 \alpha_1 x$$

In the last formula, all the quantities may be determined from ordinary logarithmic tables, so that the calculation of the voltage distribution on any transmission line for one particular load by means of the rigid hyperbolic theory is a very simple matter,

and is well within the capabilities of any electrical engineer. The current at any point is directly proportional to the voltage, and the volt-amperes is equal to the product of the current and the voltage. The power factor is uniform.

In order to illustrate the application of these formulas, the transmission line in Table IV has been calculated for a receiving end voltage of 115,500 and for a load having an impedance equal to the surge impedance. The computation is shown in Table A. In Table B, the results are tabulated in such a manner that they may be compared with the results given in Table IV. It should be noted that the points used in Tables IV and B are not quarter wave length points.

A comparison of the results in Tables IV and B show some discrepancies, but the differences are not beyond reason. It is therefore not unreasonable to believe that Mr. Goodwin's general conclusions respecting the qualitative operation of transmission lines, loaded with the "critical load" as used in the paper, will apply when the load having an impedance equal to the surge impedance of the line is used as the basis of the argument, to the same extent as they apply to the conditions considered by Mr. Goodwin. The quantitative relations will, of course, be different.

The load mentioned in this discussion may be obtained from formulas which are obtained from formulas (3) and (4) of the paper by substituting the expression

$$\sqrt{\frac{r + j l \omega}{g + j c \omega}} \quad \text{for the expression } \sqrt{L/C}. \quad \text{Thus, from formula}$$

(3) we obtain

$$(\text{kv-a.})_n = \frac{1000 e^2}{\sqrt{\frac{r + j l \omega}{g + j c \omega}}}$$

and from (4)

$$\text{kv-a.} = \frac{1000 E^2}{\sqrt{\frac{r + j l \omega}{g + j c \omega}}}$$

TABLE A

OPERATING CHARACTERISTICS OF VERY LONG TRANSMISSION LINE AT UNIFORM POWER FACTOR

3. "Artificial Electric Lines; Their Theory, Mode of Construction, and Uses"—A. E. Kennelly, A. M., Sc. D., pages 43 to 46.

delay in making this most helpful method generally available to the profession.

Mr. Evans first takes exception to the first statement under the caption "Summary" which is in regard to the most economical transmission of power over a long distance line.

First it should be noted that this is *quoted* from Mr. Thomas's paper and is not a direct statement by the author. It has only been inserted to complete better the picture which Mr. Thomas paints. "Qualitative Analysis" deals with the qualitative operating characteristics of transmission lines and carefully avoids quantitative statements. The author hopes to present something in a future paper on the subject of efficiency of transmission which will develop the subject fully, logically and in a new light. But since Mr. Evans has gone to such length on this point it may be well here to discuss the matter further that others be not misled. Notice first that Mr. Thomas's statement is in regard to "a long-distance line," while Mr. Evans' example is concerned only with a short line 125 miles long.

Measuring from Mr. Evans's Fig. 1, it would appear that his claim is that the transmission would be more economical with the current at the receiving end lagging behind the voltage at an angle of 10 deg., which corresponds to a power factor of 0.9848. This means an increase in current at the receiver end of 1.6 per cent and a total increase in losses of about 3 per cent. His statement that the generator voltage would be higher under his conditions is correct, according to the rules of "Qualitative Analysis." It would therefore appear that Mr. Thomas's statement is more accurate than Mr. Evans's deduction from his diagram.

The circle diagram for long transmission lines has often been called into question and various efforts have been made to correct its deficiencies. It is based on assumptions. In an exposition of the circle diagram in the *Electric Journal* for December, 1921 by Mr. R. D. Evans and another author, there is given on page 533 a derivation of the "loss circle diagram." One of the bases is the statement: "the losses *neglected*—are *practically constant*" (italics by present author). In general, the derivation is so incomplete and involved as to make checking most difficult. But in opening this article on the circle diagram, the authors state: "The primary object of an approximate graphical solution is not one of accuracy—the rigid mathematical solution may be applied to the particular case with any further degree of accuracy that may be desired." It is but natural to suggest that Mr. Evans apply a rigid mathematical solution to his assumed load and line and prove thereby that the lagging power factor condition is more efficient than the unity power factor condition suggested by Mr. Thomas from the simple, fundamental, physical conception. When he has thus demonstrated to his own satisfaction that Mr. Thomas is correct, he might try a few degrees leading (about half the small angle of the impedance triangle of his assumed short line). Mr. Evans has not given sufficient data on his assumed line to allow others to do this.

Mr. Evans then calls upon his circle diagram as given in his Fig. 2 to prove the "instability" of some of the long lines given as examples by the author to show some of the characteristics of long lines operating at fixed critical loads. The author's calculations were made by the rigid mathematical formulas on which Mr. Evans' circle diagram is supposed to be founded. Is it but reasonable to suggest that Mr. Evans again follow his own advice and check the conditions which he proposes and the conditions which the author has suggested by the rigid mathematical formula. Fortunately Mr. J. R. Dunbar has in later discussion shown the results of repeated calculations on one of the lines calculated by the author which for the present purposes check with very fair accuracy, particularly in regard to the question of power factor.

But this aside. Acknowledge that starting with certain receiver conditions it is possible to figure the conditions at a

supply point 100 miles or several hundred miles distant; again make this point and load the receiver conditions for another length of line; repeat this as often as desired. What is there then to question in the result if each step has been made accurately? How can a "diagram," based on very short lines and modified by approximation for longer lines, be called upon to over-throw the result with one stroke of the compasses?

Enough has probably already been said to counter Mr. Evans' third point of "the desirability of the circle diagram," etc. His discussion rather proves the desirability and necessity for the use of "Quantitative Analysis" based on simple, physical conceptions by all transmission engineers, even though they may be expert with various methods of "Qualitative Analysis."

Just one more point—a warning is necessary in this connection: The greatest care must be used in the application of any formulas, which have any assumptions whatsoever, to lines operating at the critical load near unity power factor.

Mr. Karapetoff called upon the author for proof of the statements on the first page and suggested the possibility of proving them by making many calculations on his "Heavisidion." If the section of the paper headed "Vector interpretation of critical load transmission" is studied sympathetically and thoroughly the bases of the rules given on the first page will readily be understood. As for the matter of checking by actual calculation, the author has checked these rules by numerous calculations and by comparing with the results of accurate calculations by others, and complete agreement has always been found.

As for the derivation of the rules from the hyperbolic formula, Mr. J. R. Dunbar has very kindly contributed in discussion such a derivation. Mr. Dunbar notes that the rules in the paper are approximations for the rigid formula. This is readily agreed. The rules are given in a simple form and are stated as applicable to "transmission lines of *present commercial lengths*."

The last of Mr. Karapetoff's discussion is fully covered by noting again that the rules are given to apply only to "transmission lines of present commercial length."

In regard to Dr. Steinmetz's discussion, the author has little to say except to thank him for his confirmation of the author's work and his fuller explanation of many of the interesting points. However, in his last paragraph he states "we may assume 360 ohms as the surge impedance of a line conductor against another line conductor." In view of the values given in Table I of the paper for various high-voltage transmission lines, it would appear that while 400 may be a very little above the average there are no lines which have a value so low as 360. Therefore, the factor 0.4 in the approximate formula for the critical load would seem to be entirely satisfactory.

Mr. Fortescue's discussion, as does a section of Mr. Evans's, dealing with distributing synchronous condensers along the line really goes by the whole point of the paper and shows again the necessity for "Qualitative Analysis" and understanding the reversal of conditions which take place when the load on a line passes the critical load.

In Mr. Fortescue's seventh paragraph he says "but for a practical operating line," etc. The author maintains that the information which he has set forth in this paper is much more practical and useful than any discussion on the use of synchronous condensers distributed at different points on a long transmission line. We have with us now hundreds of transmission lines showing the characteristics expounded in this paper, but we have not as yet one transmission line with synchronous condensers scattered along it at various points for the delivery of reactive power.

The author fully appreciates the application that may be made of synchronous condensers in this manner and has considered them in certain definite applications but he maintains that their

The "Heavisidion"

A Computing Kinematic Device for Long Transmission Lines¹

BY VLADIMIR KARAPETOFF

Fellow, A. I. E. E.
Professor of Electrical Engineering, Cornell University

Subject of the Paper.—A kinematic computing device is described which can be set to represent vectorially the voltage and the current at any point of a long transmission line with uniformly distributed properties and with a given load. The device has been named after Oliver Heaviside who was among the first to establish and to solve the fundamental differential equations of such a line. The parts of the device are made to assume at will different positions corresponding to different points on the line. The constants of a line to be represented by the device are adjustable at will, and a complete set of performance curves of a given transmission line can be obtained. Conversely, by a few simple trials, the best constants of a line and the necessary kv-a. of a synchronous condenser may be found, to give the required performance characteristics. The current, the voltage, and the power factor (or the phase angle) can

be read off directly on the device for any desired point of the line, including the generator and the load end.

Results of computations are shown for two transmission lines, 1000 and 300 miles long, values having been obtained in the usual tedious way by means of hyperbolic functions of a complex variable, and also read off directly on the Heavisidion. The agreement is as good as could be desired, showing that the device is reliable and that a considerable saving in time is possible with it. The device consists mainly of steel and celluloid bars, proportional dividers, parallel double tongs, and other simple kinematic linkages. Two sharp-edged wheels are used, similar to those used in planimeters. The parts are so combined as to satisfy the familiar exponential vectorial expressions for the sinusoidal voltage and the current, the independent variable being the distance from one of the ends of the line.

A. INTRODUCTION

The Meaning of the Word Heavisidion. The device was named after the noted English scientist and engineer, Oliver Heaviside, Honorary Member of the A. I. E. E., who was among the first to establish and

What the Heavisidion is. A combination of movable bars and linkages (Figs. 1 and 2) which can be set to represent, to a certain scale, the current and the voltage at any point of a line as vectors, in their proper relative phase position. The line constants are taken into

FIG. 1—THE FIRST EXPERIMENTAL HEAVISIDION

to solve the fundamental differential equations of an electric line with distributed resistance, inductance, capacitance, and leakance.

1. The investigation upon which this paper is based was supported by a grant from the Heckscher Foundation for the Advancement of Research, established by August Heckscher at Cornell University.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 14-17, 1923.

account by properly setting the adjustable portions of the device. The parts of the device are kinematically so constrained that when it is set correctly for one point of the line, say the receiving end, it gives correct values for any other point. Each degree on the large circular scale corresponds to a certain number of miles along the line. By moving the two pointers by the same number of degrees in the opposite direc-

tions, the device is reset for another desired point on the line.

The Purposes of the Device. (1) To enable a designer to predetermine quickly and accurately the voltage

account; without hyperbolic functions, without complex quantities, and without short-cut approximate methods. (2) To enable a designer or an operating engineer to determine quickly the effect of a proposed

FIG. 2—THE TOP VIEW AND THE SIDE VIEW OF THE HEAVISIDION WITH THE PARALLEL DOUBLE-TONGUE LEFT (SEE FIGS. 1 AND 4.)

and current characteristics of a transmission line, at any desired load and terminal voltage, taking the distributed capacitance and leakage correctly into

change in the line constants, in the load, in age, in the length of the line, etc., upon ing distribution of current and voltage

line. (3) To make it possible to select the proper kv-a. of a synchronous condenser at a desired point of the line, so as to obtain the desired line voltage characteristics. (4) For some purposes to take the place of the involved analytical theory and to permit to visualize the actual electrical relationships along the line. (5) To add the judgment of the eye and the skill of the hands to the purely mental ability in studying a line problem for which the device can be used. (6) To enable an investigator or a student to familiarize himself with the line characteristics (under steady conditions) as if an artificial line of widely adjustable constants, and any desired load and voltage, were available for tests.

Other Kinematic Devices. The Heavisidion is one of the several kinematic devices developed by the writer, for representing the performance characteristics of various kinds of electrical machinery and circuits. The other devices are as follows:

1. A device for representing the performance of an electromagnetic clutch used in the Owen magnetic car; *Sibley Journal of Engineering*, Jan. 1918, Vol. XXXII, p. 550.

7. A device for the study of transient phenomena in lines (in preparation).

Limits of Current and Voltage. Being a graphical device, the Heavisidion requires certain scales to be chosen for each particular problem. A convenient scale has to be selected for volts and another for amperes. The device can therefore represent the performance at a small load as well as at one which runs into hundreds of thousands of kilowatts; of an 11-kv. line as well as of one designed for 550 kilovolts. As in any graphical device, there may be some limitations due to the finite lengths of the bars, necessitating a change in the chosen scale. However, the device shown in Fig. 1 has been tested for lines up to 1000 miles long and found to be of sufficient accuracy, as will be seen from the second numerical example below.

B. GENERAL DESCRIPTION OF THE HEAVISIDION

The first complete Heavisidion, shown in Figs. 1 and 2, was built in the writer's experimental shop, in Cornell University, during the year 1922. Most parts are made of flat steel bars, or of celluloid bars, and the principal dimensions are given in the table below

FIG. 3—A SIDE VIEW SHOWING AN IMPROVED CENTER PIECE SLIDERS AND WHEEL SUPPORT

2. The Secomor, a device which represents the performance of a polyphase series-connected commutator motor; A. I. E. E. TRANS., 1918, Vol. XXXVII, Part I, p. 329.

3. The Indumor, a device which represents the performance of a polyphase induction motor, and its modification, the Shucomor, which represents the performance of a shunt-connected commutator motor; A. I. E. E. JOURNAL, 1922, Vol. XLI, p. 107.

4. The Blondelion, a device which represents the operating characteristics of a polyphase synchronous generator or motor.

5. An Integraph based on parallel double-tongs, for a mechanical integration or differentiation of a given curve. This device finds its usefulness in problems of hunting of machinery, fly-wheel design, ship stability, etc. *Optical Soc. of Amer. and Review of Scientific Instruments, Journal*, 1922, Vol. VI, p. 978.

6. The C. P. S'er (named after Dr. C. P. Steinmetz), a device for the automatic addition of impedances and admittances (description in preparation).

In the writer's opinion, the size of the device could be considerably reduced without impairing its accuracy, if the instrument were made with the precision of, say, a planimeter. The grooved bars and the improved slider, shown in Fig. 3, are of about one-half the size of those shown in Figs. 1 and 2.

THE PRINCIPAL DIMENSIONS OF THE HEAVISIDION

Part or distance (Fig. 2)	Length in cm.	Cross-sec. in mm.
Circular scale, radius.....	80	..
Bars A A' and B B'.....	80	25 × 3
Bars C C' and M M'.....	65	10 × 1.5
Bars D H and F K.....	60	10 × 1.5
Bars B D, B F, K A and A H.....	30	10 × 1.5
Rod p q.....	80	5 (dia.)

The Voltage. In the side view (Figs. 2 and 3) O O' is a vertical axis about which the guide sleeves G_a and G_b can revolve. In the top view the steel bars A A' and B B' are shown passing through these guides. Each guide is lined on the inside with steel balls to reduce the

able link $D' C'' F'$ may be added to the double parallelogram and the connection to the parallel double tongs made at C'' , instead of C . It is also possible to turn the vector OM by the angle θ so as to represent the true phase position of the current. This can be done, for example, by using the generalized proportional dividers described in the paper on the Indumor (*loc. cit.*, p. 111).

C. AUXILIARY CHARTS OF LINE CONSTANTS

In order to use the Heavisidion for a line of given

current vector I , Figs. 2 and 7; it is proposed to call this angle the *differential angle* of the line.

z_s , the *surge impedance* of the line, which determines the scale of the line current;

β , the *wave length constant* of the line.

The angle β is the angle by which each of the bars, AA' and BB' , must be turned (in the opposite directions) in order to obtain a setting for a point of the line one km. or one mile distant from the given setting. In other words, β is measured in degrees (or radians)

Fig. 5

FIG. 5—A CHART OF VALUES OF IMPERFECTION ANGLE τ_0 AND OF DIFFERENTIAL ANGLE θ_0 FOR LINES OF ZERO LEAKAGE ($g = 0$); IN THIS CASE $\theta_0 = \tau_0$. Examples: $x/r = 3$, $\tau_0 = 10$ DEG. 13 MIN.; $x/r = 0.4$, $\tau_0 = 34$ DEG. 06 MIN.

constants (resistance, reactance, capacitance and leakage, all per unit length), it is necessary to determine the following auxiliary constants (see also the list of symbols at the end of the paper):

τ , the so-called *imperfection angle* of the line; the sharp-edged wheels a and b are set at this angle (Fig. 8).

θ , the angle between OM and the true direction of

per unit length. If β is measured in degrees, then (360 deg./ β deg) gives the number of miles for which each of the bars is turned by 360 deg. The bars are then again in their original positions and the values of current and voltage repeat themselves. The length 360 deg./ β deg. is therefore called the wave length of the line; it depends upon the line constants and the

FIG. 6—A CHART OF VALUES OF SURGE IMPEDANCE z_0 AND OF THE WAVE LENGTH CONSTANT β_0 , FOR LINES OF ZERO LEAKANCE ($g=0$).

frequency. In the actual use of the Heavisidion it has been found convenient to compute the value of β directly for each 100 miles, so as to avoid small quantities; this should be kept in mind when using the values of β_0 found from Fig. 6.

In most practical cases of long-distance high-tension transmission lines the distributed leakage is negligible. The symbols for the foregoing four constants are then provided with the subscript zero. Thus, τ_0 , θ_0 , z_0 and β_0 are the values corresponding to zero leakage. These values may be obtained directly from the charts shown in Figs. 5 and 6, without any computations. In rare cases when the leakage has to be considered, a small correction is necessary, as is explained below.

FIG. 7—THE RELATIONSHIP BETWEEN THE COMPONENT VOLTAGES V_a AND V_b , THE TOTAL VOLTAGE E , AND THE VECTOR $Z_s I$.

Knowing the size and the material of the line conductors, their spacing, and the frequency of the supply, the following quantities *per phase per mile* can be either computed or taken directly from tables available in various handbooks, etc.:

- r the effective resistance, in ohms per mile;
- x the inductive reactance, in ohms per mile;
- b the capacitive susceptance, in mhos per mile.

The tables arranged by Mr. Wm. Nesbit and published in *The Electric Journal*, 1919, Vol. XVI, pp. 317 to 322, will be found convenient in that the ratio x/r is tabulated directly. These tables will be also found in the "Electrical Characteristics of Transmission Circuits," Reprint 82, Feb. 1922, on pages 12 to 19 (published by the Westinghouse Electric & Manufacturing Co.).

Knowing x/r , the values of θ_0 and τ_0 (which are equal to each other for a line devoid of leakage) can be read off directly on the chart in Fig. 5. To find z_0 , it is necessary first to compute the ratio x/b . Referring to Fig. 6, a straight edge is then placed between the known values of τ_0 and x/b on the corresponding scales, and the value of z_0 is read off on the second scale from the left. Then the product $x b$ is computed and the straight edge is laid between the proper values of τ_0 and $x b$ on the outside scales. The corresponding value of β_0 is read off on the second scale from the right.

D. THE USE OF THE HEAVISIDION AND NUMERICAL EXAMPLES

Example 1. On p. 103 of the above mentioned Reprint of Nesbit's articles, or in the *Electric Journal*, 1920, Vol. XVII, p. 300, the following example is given: A three-phase, 60-cycle, 300-mile, transmission line; No. 000 stranded copper conductor spaced 10 by 10 by 20 ft. (equivalent delta 12.6 ft.); temperature 25 deg. cent. The receiver load is 18,000 kv-a. at 90 per cent power factor, lagging; the receiver voltage is 104 kv. It is required to determine the voltage, the current, and the power factor at the generator end. The line leakage is to be neglected.

Preliminary Computations. (a) The receiver voltage to the neutral is $E_2 = 104 \sqrt{3} = 60.05$ kv; the receiver current per phase is $I_2 = 18000 / (3 \times 60.05) = 99.92$ amperes. The corresponding phase angle is $\phi_2 = \cos^{-1} 0.90 = 25$ deg. 50 min.

(b) For the given conductor and spacing we find by interpolation the following values per phase:

Reprint No. 82. *Electric Journal* 1919, Vol. XVI.

page 13 page 317 table V $x = 0.83$ ohm per mile
page 15 page 319 table VII $x/r = 2.37$ numeric
page 18 page 322 table X $b = 5.21$ micro-mhos.
Hence, $x b = 4.24 \times 10^{-6}$ miles⁻²; $x/b = 0.159 \times 10^6$ ohm².

(c) Using these values, we find from the charts in Figs. 5 and 6, as explained above: $\tau_0 = \theta_0 = 11$ deg. 26 min.; $z_0 = 416$ ohms; $\beta_0 = 12.2$ deg. per 100 miles.

Setting of the Heavisidion. (d) Select a convenient voltage scale; in this particular case it was taken as 3 kv. per cm. Set $C C'$ (Fig. 2) along the reference line marked on the table and make $O C = 60.05/3 = 20.02$ cm.; tighten the setscrew f . When setting the point C , it is necessary to move points A and B and therefore the bars $A A'$ and $B B'$. This adjustment should be made carefully and the wheels a and b slightly lifted by holding the device at C , so as not to scratch the table.

(e) By means of the protractors at A and B , set the wheels a and b at the angle $\tau_0 = 11$ deg. 26 min. in such a direction (Fig. 8) that the lengths $O A$ and $O B$ (Fig. 2) will increase when the bars are rotated counter-clockwise.

(f) Set the slide G_m at the angle $\theta_0 = 11$ deg. 26

surge impedance z_s ; with small leakage it may be taken as equal to z_0 without leakage.

Knowing the above constants, the Heavisidion was set for a given receiver load and voltage, and by moving the bars in steps of 200 miles the "primed" values were obtained given in the table below.

L miles	E kilovolts	E'	I amperes	I'	ϕ	ϕ'	Cur- rent
0	50.0	50.0	25.0	25.0	25 deg. 00 min.	25 deg. 00 min.	lags
200	48.8	49.3	49.8	50.7	58 deg. 33 min.	58 deg. 15 min.	leads
400	40.7	40.05	94.7	95.0	65 deg. 09 min.	65 deg. 00 min.	leads
600	28.9	29.0	128.5	128.5	50 deg. 01 min.	50 deg. 00 min.	"
800	24.3	24.6	143.7	146.0	10 deg. 24 min.	9 deg. 00 min.	"
1000	34.7	36.0	140.0	142.5	19 deg. 21 min.	18 deg. 30 min.	lags

The unprimed values were computed by Mr. Pernot using exponential expressions (*ibid.*, p. 107). Here again the agreement between the computed and measured values is quite satisfactory, especially considering the great length of the line.

Procedure with Extra-Long Lines. The circular scale of the Heavisidion as actually built (Fig. 1) extends only up to about 100 deg. on each side of the center zero. Therefore, for an extra-long line, or at a high frequency, the bars $A A'$ and $B B'$ (Fig. 2) may be at the limits of the scale before the other end of the line has been reached. In such a case the Heavisidion is used as *its own optical image*.

Referring again to Fig. 1, let the pointers of the main bars be somewhere on the lower (non-existing) semicircle of the scale. Imagine a plane vertical mirror passing through both 90 deg. points and the center line OO' of the device, the reflecting plane being turned towards the fictitious semicircle. The optical image of such an impossible setting lies in the upper semicircle, and therefore can be realized on the actual device, being in its real range. While the bar $A A'$ moves counter-clockwise, its image moves clockwise. The reverse is true for the bar $B B'$.

Therefore, when the bars get near or past the 90 deg. points, proceed as follows: Tighten the setscrews of guides G_a and G_b , and note the amount by which the bars have passed the 90 deg. points, for example, $+\rho_1$ and $-\rho_2$ degrees, respectively. Turn the wheels a and b by the angle τ on the other side of zero so that the lengths OA and OB would increase if rotated clockwise. Move the bars to the positions corresponding to $-\rho_1$ and $+\rho_2$ degrees with respect to the 90 deg. points. Loosen the setscrews and continue moving each bar in the direction opposite to its previous motion. By this means the range of the device can be increased indefinitely.

Branch Loads. Let the Heavisidion be set for the receiver end and then the bars $A A'$ and $B B'$ rotated towards the generator end, as explained above. Let there be a branched concentrated load somewhere on the line. Having come to this point, the voltage bar

CC' is fastened so that it cannot move, while the current bar MM' and the bars $A A'$ and $B B'$ are reset to take into consideration the added branch current. Then the motion of the device is resumed as heretofore, to the next load, where the new current is added vectorially, etc.

Synchronous Condenser. Usually a very long transmission line has to have a synchronous condenser at the receiver end, in order to keep voltage fluctuations within reasonable limits. The required maximum kv-a. of such a condenser can be determined with the Heavisidion by a few simple trials. The device is set for the desired receiver voltage and for a reasonable reactive current to be supplied by the condenser, in addition to the load current. Then the bars $A A'$ and $B B'$ are turned into the position corresponding to the generator end, and the results noted. If the generator voltage is not satisfactory, the device is reset at the receiver end for a different reactive component and the new generator voltage measured. In this manner, the limits of the required reactive current are found after a few simple trials, without any complicated computations.

E. THEORY OF THE HEAVISIDION

The well-known fundamental equations of the sinusoidal alternating current and voltage in a transmission line, at a point distant s miles from the receiver end, are as follows:⁴

$$E = 0.5 (E_2 + Z_s I_2) e^{\alpha s} e^{j\beta s} + 0.5 (E_2 - Z_s I_2) e^{-\alpha s} e^{-j\beta s} \quad (1)$$

$$I = 0.5 (E_2 Z_s^{-1} + I_2) e^{\alpha s} e^{j\beta s} - 0.5 (E_2 Z_s^{-1} - I_2) e^{-\alpha s} e^{-j\beta s} \quad (2)$$

For the meaning of the symbols see the list at the end of the paper. Multiplying eq. (2) by Z_s gives

$$Z_s I = 0.5 (E_2 + Z_s I_2) e^{\alpha s} e^{j\beta s} - 0.5 (E_2 - Z_s I_2) e^{-\alpha s} e^{-j\beta s} \quad (3)$$

Combination of E and $Z_s I$ out of V_a and V_b . Let us introduce, for the sake of abbreviation, component voltages V_a and V_b , where

$$V_a = (E_2 + Z_s I_2) e^{\alpha s} e^{j\beta s} \quad (4)$$

$$V_b = (E_2 - Z_s I_2) e^{-\alpha s} e^{-j\beta s} \quad (5)$$

For a given point on the line, V_a and V_b are vectors measured in effective volts. Eqs. (1) and (3) become

$$E = 0.5 (V_a + V_b) \quad (6)$$

$$Z_s I = 0.5 (V_a - V_b) \quad (7)$$

These relations are shown graphically in Fig. 7.

4. See, for example, C. P. Steinmetz, "Transient Phenomena," Section III, Transients in Space; F. E. Pernot, "Electrical Phenomena in Parallel Conductors," pp. 96-98. In the following equations the customary dots under E and I , to denote vectors, are omitted.

relationships of the various constants of a transmission line, in order to make clear the underlying theory of these charts. For the elementary theory of electric lines the reader is referred to numerous works on the subject, among others to those mentioned above.

The Imperfection Angle Expressed Through the Line Constants. The factors α and β can be expressed through the linear constants of the line; therefore the angle τ , eq. (16), can also be expressed through these constants. Referring to Fig. 9, we introduce the *resistance angle*, θ_r , defined by the expression

$$\tan \theta_r = r/x \quad (17)$$

and the *leakage angle*, θ_g , defined by

$$\tan \theta_g = g/b \quad (18)$$

For a line devoid of resistance and leakage $\theta_r = \theta_g = 0$. For the series impedance Z and the shunted admittance Y of the line, per unit length, we can therefore write

$$Z = z e^{j(0.5 \pi - \theta_r)} \quad (19)$$

$$Y = y e^{j(0.5 \pi - \theta_g)} \quad (20)$$

FIG. 9—THE RESISTANCE ANGLE AND THE LEAKAGE ANGLE OF THE LINE

For the complex propagation constant we have

$$\alpha + j\beta = \sqrt{ZY} = \sqrt{zy} e^{0.5 \pi - 0.5 j(\theta_r + \theta_g)} \quad (21)$$

$$\text{Hence } \alpha = \sqrt{zy} \sin 0.5(\theta_r + \theta_g) \quad (22a)$$

$$\beta = \sqrt{zy} \cos 0.5(\theta_r + \theta_g) \quad (22b)$$

In the expression for β it is sometimes convenient to use x and b in place of z and y . From Fig. 9 we have

$$z = x / \cos \theta_r; y = b / \cos \theta_g \quad (23)$$

The foregoing expression for β then becomes

$$\beta = \sqrt{\frac{xb}{\cos \theta_r \cos \theta_g}} \times \cos 0.5(\theta_r + \theta_g) \quad (24)$$

Substituting the values of α and β from eqs. (22) in eq. (16), gives

$$\tan \tau = \tan 0.5(\theta_r + \theta_g)$$

from which, since τ is less than 90 deg.,

$$\tau = 0.5(\theta_r + \theta_g) \quad (25)$$

Thus, knowing the angles θ_r and θ_g from eqs. (17) and (18), the imperfection angle τ , at which the wheels a and b must be set, can be computed from eq. (25), without first determining the values of α and β .

Surge Impedance and its Angle Expressed through the Line Constants. By definition, the surge impedance of a line

$$Z_s = z_s e^{-j\theta} = \sqrt{Z/Y} \quad (26)$$

where Z and Y are expressed by eqs. (19) and (20) respectively. Z_s is a complex quantity, and is characterized by its magnitude z_s and the phase angle θ . It is convenient to use the minus sign before θ , because in ordinary power transmission lines this operator turns the current vector clockwise; compare the directions of Z, I and I in Figs. 2 and 7. Substituting the values of Z and Y in eq. (26), we get

$$z_s e^{-j\theta} = \sqrt{z/y} e^{-0.5 j(\theta_r - \theta_g)} \quad (27)$$

from which

$$z_s = \sqrt{z/y} \quad (28)$$

and

$$\theta = 0.5(\theta_r - \theta_g) \quad (29)$$

It is proposed to call θ the *differential angle*, or the *distortion angle* of the line. It characterizes the difference between the imperfection angle θ_r due to the line resistance and the imperfection angle θ_g due to the leakage. When $\theta_r = \theta_g$, $\theta = 0$, and from eqs. (17) and (18) we get the familiar condition used in telephone engineering for a distortionless line: $r/L = g/C$.

It is sometimes convenient to express z_s in terms of x and b . Using eqs. (23) in eq. (28), we obtain

$$z_s = \sqrt{\frac{x \cos \theta_g}{b \cos \theta_r}} \quad (30)$$

Case of Zero Leakage. In most practical cases of power transmission lines it is permissible to put $g = 0$, unless the performance is desired in stormy weather, with poor insulation, excessive corona loss, or other abnormal conditions. When $g = 0$, θ_g is also equal to zero, and the foregoing expressions are somewhat simplified. The symbols which refer to this specific case are provided with the subscript zero. Eq. (25) gives

$$\tau_0 = 0.5 \theta_r \quad (31)$$

$$\text{and from eq. (29) } \theta_0 = 0.5 \theta_r \quad (32)$$

Consequently

$$\tau_0 = \theta_0 = 0.5 \theta_r = 0.5 \tan^{-1}(r/x) \quad (33)$$

The chart in Fig. 5 is constructed to represent this

relationship, and saves the time of looking up trigonometric tables. From eq. (24)

$$\beta_0 = \sqrt{(x/b) \cos 2\tau_0 \times \cos \tau_0} \quad (34)$$

and from eq. (30)

$$z_0 = \sqrt{\frac{(x/b)}{\cos 2\tau_0}} \quad (35)$$

The alinement chart in Fig. 6 gives values of β_0 and z_0 for known values of τ_0 , (x/b) , and (x/b) , in accordance with eq. (34) and (35), and makes the actual use of these equations unnecessary. The scales are logarithmic so that a product is replaced by a sum. It would lead too far to explain here in detail the laying out of an alinement chart; it suffices to state that the chart in Fig. 6 takes the place of eqs. (34) and (35), and thus saves considerable time in obtaining the values of β_0 and z_0 .⁸

Corrections for Small Leakage. Even under extreme conditions of transmission line operation, the uniformly distributed leakage is comparatively small, and the angle θ_0 is not over 2 or 3 degrees. Therefore, the above described charts can still be used, and then small theoretical corrections applied to the values read off. For this purpose the angle θ_0 must be computed from eq. (18). Comparing eqs. (25) and (31) we have

$$\tau = \tau_0 + 0.5 \theta_0 \quad (36)$$

Thus, to the value of τ_0 obtained from Fig. 5 for the case of no leakage, a small angle, $0.5 \theta_0$, must be added to obtain the actual value of τ with the leakage. Similarly, comparing eqs. (29) and (32) we get

$$\theta = \theta_0 - 0.5 \theta_0 \quad (37)$$

We thus see that when leakage is present, the angles τ and θ are no more equal to each other.

In eq. (30) $\cos \theta_0$ can still be assumed to be equal to unity, so that with a small leakage $z_s = z_0$, and the expression (35) needs no correction. It must be noted that in this expression the angle τ_0 is used, and not τ . In other words, the value of z_0 obtained from Fig. 6 may be used with small leakage as well as without leakage.

In eq. (24) $\cos \theta_0$ may also be put equal to unity, thus giving

$$\beta = \sqrt{(x/b) \cos 2\tau_0 \times \cos \tau} \quad (38)$$

Comparing this expression with eq. (34), we get

$$\beta = \beta_0 (\cos \tau / \cos \tau_0) \quad (39)$$

In other words, β_0 can be taken from Fig. 6 and the value so obtained corrected in the ratio of $\cos \tau$ to $\cos \tau_0$.

* * * *

The writer's assistant, Mr. O. K. Marti, actually built the device shown in Fig. 1 and performed all the measurements described above. To him credit is also due for several mechanical details and for the drawings and charts used in this paper. The author wishes to express to him his sincere appreciation of the valuable

assistance rendered. Mr. C. H. Dagnall, an instructor in Electrical Engineering in Cornell University, made a preliminary investigation of the possibilities of the proposed principle and performed some valuable computations and measurements. The author is under obligation to him for his active interest in this problem and for the use of some data from his thesis. Professor A. E. Wells, of Mechanic Arts, Mr. D. B. Green, Foreman of Machine Shop, and Mr. G. A. Culligan, Mechanician, all of the staff of the College of Engineering, gave generously of their time and skill in the making of the parts of the device, and it is only through their hearty cooperation that the device was completed within a comparatively short time.

LIST OF SYMBOLS

b	capacitive susceptance, in mhos per mile
E	voltage vector at the point under consideration, in effective volts
E_2	same at the receiver end
f	frequency, in cycles per second
g	leakage conductance (leakance), in mhos per mile
I	current vector at the point under consideration, in effective amperes
I_2	same at the receiver end
$j = \sqrt{-1}$	
o	subscript meaning "no leakage"
r	effective resistance, in ohms per mile
s	distance from the receiver end to the point under consideration, in miles
V_a, V_b	component voltage vectors defined by eqs. (4) and (5), in effective volts
V_{ar}, V_{br}	same at the receiver end
x	inductive reactance, in ohms per mile
$Y = y e^{j(0.5\pi - \theta_0)}$	admittance of the line, in mhos per mile
$Z = z e^{j(0.5\pi - \theta_r)}$	impedance of the line, in ohms per mile
$Z_s = z_s e^{j\theta} = \sqrt{Z/Y}$	surge impedance of the line, in ohms
$Z_0 = z_0 e^{-j\theta_0}$	same without leakage
α	attenuation constant of the line, a numeric per mile
β	wave-length constant of the line, in radians per mile; in numerical applications and in Fig. 6, β is in degrees per 100 miles
β_0	same without leakage
e	base of natural logarithms
θ	phase angle of the impedance Z_s , with the minus sign, or the differential angle of the line, in degrees or radians
θ_0	same without leakage
θ_r	leakage angle, in degrees or radians
θ_s	resistance angle, in degrees or radians
τ	imperfection angle of the line, in degrees or radians, defined by eq. (25).
τ_0	same without leakage

A New Method for the Routine Testing of Alternating-Current High-Voltage Paper-Insulated Cable

By HOWARD S. PHELPS and E. DEAN TANZER

Associate, A. I. E. E.

Associate A. I. E. E.

Both of the Philadelphia Electric Company

Review of the Subject.—The usual methods of testing alternating-current high-voltage paper-insulated cables are based upon the ability of the insulating material to withstand excessive potentials in order to determine its condition. Accordingly, these methods are not suitable for routine tests imposed for the purpose of determining the degree of deterioration existing in any particular cable.

In an effort to develop a routine test, which will serve to detect an impending fault, use has been made of the kenotron as the source of high-potential direct-current. By means of it a large volume of data has been secured concerning the input-current, for a cable, as a function of time after complete electrification at a constant high potential. These data when plotted, as curves, show by their shape the condition of the cable insulation.

Curves showing a sharp decrease in the magnitude of input-current during the first minute and a gradual but persistent rate of decay for the succeeding six or seven minutes indicate that the insulation is in an acceptable condition from the operating point of view.

Curves showing little, if any, decrease or a persistent tendency to increase during the time interval of the test indicate that the insulation has deteriorated to such a point that the cable may be expected to

fail at an early date if retained in service. The degree of deterioration is indicated first: by the time which has elapsed since complete electrification before the increase occurs, and second: by the sharpness of the upward trend of the curve in any instance.

The value of this method of testing has been demonstrated by its actually having detected a considerable number of impending cable faults before they became a menace in operation.

Additional refinements in the methods of measuring the input-current for different classes of cables may be desirable. Further investigations are being carried on to determine this necessity. Investigations of certain theoretical features are also being carried on. These include, among other things, oscillographic studies of the input-current and voltage under test conditions.

INTRODUCTORY—THE PROBLEM

WITH the expansion of underground transmission alternating-current networks, as regards both extent and operating voltages, the problem of determining the condition of the feeders has become more and more complex. The size and cost of alternating-current equipment for testing cables in modern underground systems is a matter of no small importance. With the high-transmission voltages and increased feeder lengths, these two factors approach limits which are almost prohibitive.

Also, the usual alternating-current test schemes have only determined the ability of a specific cable to withstand a particular test voltage; usually much in excess of that in normal operation. In our opinion a more desirable test method must include not less than the following features:

1. Should, if possible, be capable of detecting abnormal conditions in a cable at a sufficiently early date to permit of their location and elimination prior to the time at which they would constitute a menace to the system.

2. It should be effective at an impressed potential sufficiently low to insure that the insulating material will not be over-stressed.

3. Simplicity.

Due to the desire to develop a test, independent of the actual destruction of the material, to determine its acceptability, no consideration has been given the

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 14-17, 1923.

question of relative effects of test voltages impressed on cables by the kenotron or by the usual alternating-current tests; *i. e.* the ratio of kenotron to alternating-current potential for equal electrical stresses on the cable has not been considered in this investigation. Also, no attention has been given the problem of determining the geographical location of any particular fault.

Accordingly we have, for over four years, been investigating the possibility of developing such a test method. Because of certain rather outstanding conditions existing in the alternating-current feeders for the Edison system, and the necessity of safeguarding against interruptions due to cable failures, that portion of the transmission network was utilized in the study.

At the time this study was inaugurated The Edison District of The Philadelphia Electric Company was supplied with energy principally by means of 6,000-volt, a-c., 60-cycle, two-phase, three-conductor underground transmission feeders. These feeders constituted direct ties between the generating and substations. They had been installed for a number of years and were manufactured prior to the production of low dielectric loss cables. The cables referred to are practically all 250,000 cir. mil cross-section, insulated with 5/32-in. by 5/32-in. paper impregnated with rosin oil compound. Their lengths vary between 12,000 and 18,000 feet.

The alternating-current supply system for the Edison District has been considerably augmented, beginning the latter part of 1920, by the addition of high-efficiency 13,200-volt, three-phase paper-insulated lead-covered transmission cables.

During the season of 1920 there were a number of unfortunate experiences with the operation of this portion of the transmission systems. This condition was brought about by several circumstances, among which the following may be noted:

1. The Edison load at that time was closely approaching the rated capacity of the substations and on that account if trouble developed, at any point, it was almost certain to cause a rather general interruption in the Edison District by tripping out other substations. This condition was especially true if a transmission feeder failed in service, since it probably would cause other feeders, working in parallel with it, to trip out.

2. The heavy loading of the alternating-current feeders, supplying the Edison system, tended to develop, through heating, inherent weaknesses in their insulation. Consequently, it became imperative that the utmost care be used in operating this portion of the underground system.

Several years ago The Philadelphia Electric Company secured a 60-kv., 0.1-ampere single-tube kenotron set in order to determine what, if any, possibility there was of applying a high-voltage direct-current test to underground transmission feeders to ascertain the general operating condition of such cables. The first thought was to consider the kenotron as a high-voltage megger, and from the observed values of current and impressed voltage to calculate the insulation resistance. It was immediately found that the current varied over an extremely wide range, from a large magnitude, at the instant of electrifying the cable, down to a value of $1/3$ to $1/4$ as great after several minutes of electrification. From this it was seen that a wide range of calculated insulation resistance values could be readily obtained and no decision could be made as to which of these, with respect to elapsed time, should be considered as representing the condition of the cable.

In addition to the apparent wide deviation in insulation resistance just noted it was observed that the current for a given cable when electrified to the same potential, but on different days, might vary over an extremely wide range; possibly of the order of 200 to 300 per cent variation. This latter situation is, undoubtedly, associated with the temperature of the insulating material at the time of test. However, as no feasible method was available for determining the temperature of a cable throughout its length, the combination of circumstances giving rise to wide variations of current seemed to preclude the use of the kenotron.

In view of the operating difficulties experienced in 1920, added consideration was given to the possible application of the kenotron for the purpose originally in mind; *i. e.* determination of the condition of cable insulating material. From what had been done earlier it was apparent that another method of analysis must be developed. Accordingly, consideration was given to plotting the tabular data on rectangular coordinate cross-section paper. It was hoped that the resulting

curves might indicate the general character of the cable insulation. Here again, however, the wide variation between tests on successive days seemed to complicate the problem.

The next step was to analyze some of the tabular data¹ with the hopes that the equation expressing the relation of the constants in the curve might be determined. It was very soon found that these constants apparently obeyed no definite law.

Another method of analysis employed was to plot the data on semi-logarithmic paper. The results confirmed the earlier deductions that the current-time curves were not represented by a simple mathematical function.

The very high initial value of current, together with its more or less uniform rate of decay, apparently indicated characteristics similar to those of an electrical condenser. Since it required a long period of time of the order of many minutes before the current reached a value which was reasonably constant it was also evident that the condenser characteristics exhibited were not those usually considered, but must represent a charge absorbed within the dielectric. Finally, the approximately constant value of current observed after an extended period probably represents the true leakage current through the insulation.

From the foregoing it was concluded that the shape, rather than the magnitude, of the current-time curves for any particular cable might be indicative of the condition of its insulation.

It was then determined that a large volume of data should be obtained with the hope that, possibly, its analysis might produce something more indicative than had been found in the limited material previously available. During the accumulation of this added information some rather interesting developments were noted in the results of the tests and it was deemed advisable to follow them further.

METHODS OF TESTING

Due to the many variables complicating this problem, an early effort was made to minimize their influences by conducting the kenotron tests in as nearly a uniform manner as possible.

In order that the data for different tests might be comparable, it was deemed advisable to energize the cables to the same potential in each case. Because of the age of the feeders in the 6000-volt system, an aversion to subjecting them to abnormal potential stresses, together with lack of knowledge as to what effect the kenotron tests might have upon cable insulation, it was decided to use 9000-volts, which approximates the peak value of the wave for these two-phase circuits, on 6000-volt feeders when testing them by kenotron.

As it had been decided that a study should be made to determine what, if anything, could be learned from the shape of the current-time curves, it was felt advisable to electrify the cables under test at a standard

1. Steinmetz, Engineering Mathematics.

uniform rate. It was found that the kenotron voltage could be raised very readily at a rate of 1500-volts per second, that is, a time interval of six seconds would be required in which to bring it up to test value. Therefore, this rate of electrification was adopted as standard. Operators making tests were accordingly instructed to close the high-voltage test switch at 54 seconds and to raise the voltage, as uniformly as possible, at a rate such that the test voltage, 9000 volts, would be reached at 60 seconds exactly. See Fig. 1.

In order to eliminate, as far as practicable, any unexpected effects due to adjustment of the kenotron voltage the attention of the operator was called to the necessity for care in approaching the final test value. This was done to minimize the possibility of imposing upon the cable a final voltage exceeding that desired; thereby necessitating reduction.

Having fixed the rate at which electrification should be applied, the time intervals at which readings were to be taken were arbitrarily set as follows:

Initial reading upon completion of electrification and subsequent readings at 15, 30 and 45 seconds and at 1, 2, 3, 4, 5, 6, 7 and 8 minutes after completion of electri-

FIG. 1 —METHOD OF TIMING AND CONNECTIONS USED IN DETERMINATION OF CABLE CURRENT TIME CURVES

fication; a complete time interval of 480 seconds after full test voltage had been reached.

The sequence of tests selected, see Fig. 1, was as follows:

1. Three conductors together against sheath and ground.
2. Phase A against B-C and sheath to ground.
3. Phase B against A-C and sheath to ground.
4. Phase C against A-B and sheath to ground.

Therefore, omitting the time required in changing connections and other unavoidable delays, not less than 32 minutes has been required to test a single feeder.

The foregoing instructions were prepared in concise form for the guidance of those in the Station Operating Department who were responsible for routine electrical testing, and mimeographed forms for tabulating the data were furnished. See Fig. 2. This placed the operation as nearly as possible on a routine basis, which was desirable for the purpose of learning how practical this scheme of testing would prove.

Upon receipt of the tabular material, for the several tests, from the Station Operating Department, the

NOTE: The cable is to be electrified at the rate of 1500 volts per second. To do that have Kenotron bulb working and then close high voltage d-c. switch 6 seconds before minute and raise voltage at uniform rate to test value of 9000 volts in period of time noted. When the required test voltage is reached on the minute make first reading and enter opposite "start". Make other readings 15-30 and 45 seconds and 1-2-3-4-5-6-7-8 minutes after voltage reached the test value.

Check zero reading of voltmeter and ammeter and if necessary adjust by means of small flat head screw in lower flange of instrument cases before making test.

Make note of abnormal conditions such as breakdown of spore gap.

Fig. 2

observed values of current were reduced to units of current per mile in order to facilitate direct comparison of results observed on different feeders. Much of the material has been plotted in curves similar to those which appear here.

DATA AND OBSERVATIONS

Referring to Figs. 3 and 4 which show a group of current-time curves from successive tests on feeder 112 for a period of several weeks, some interesting things may be observed.

These data are plotted to semi-logarithmic coordinates with the logarithm of the current, in milliamperes per mile at 9000 volts, as the ordinate and the time, in seconds, plotted uniformly as the abscissa. It is observed that for the tests of February 25, 1921, (Fig. 3), there is a very sharp decrease in current, from its

initial value, during the first 30 seconds. For the remainder of the eight minutes, the current decreased rather slowly and at a fairly uniform rate. It is also interesting to note the variation in the characteristics of the insulation for each of the three conductors of the cable, as brought out by the curves representing tests

FIG. 3—CURRENT-TIME CURVES

At 9000-volts electrification by kenotron feeder 112; operating voltage kv., $\frac{5 \times 5 \text{ in.}}{32}$ impregnated insulation, $3 \times 250,000 = \text{cir. mil. conductors}$; feeder length 17,487 ft.

on each of the several conductors when measured against the other two connected to the sheath and to ground.

The tests of March 11th (Fig. 3) show an entirely different situation both as to absolute value of the initial current and outline of the curves. Here again, special attention should be paid to the curves for each of the several conductors. It is noticed that the plotted data for phase B, when tested against the other two conductors and the sheath to ground, and phase C, tested in a similar fashion, have a rather uniform downward slope. On the other hand, the curve representing phase A when tested against B-C and ground, shows a decreasing characteristic during the first 60 seconds after which time the current abruptly increased. At the end of two minutes, after electrification of the cable, the value of current on phase A is only about 25 per cent less than its initial value and it continues for the balance of the eight-minute period at a magnitude not differing materially from this. Sufficient data had not been

obtained, up to the time this material was plotted, to give a clue as to what this sharp upward trend, or inversion, of the curve indicated. Subsequent events seemed to bring out this matter very clearly, for on March 22nd, or eleven days after the test under discussion, the cable failed in service.

Tests made March 25th and April 8th, (Fig. 3), after the cable had been repaired and restored to service, showed characteristics similar to those on February 25th; i. e. a gradual decay of the current from the instant of electrification.

The plotted data for tests of April 22nd, (Fig. 4), again showed that an abnormal condition existed. During the first 60 seconds the current for all three phases, tied together and tested against the sheath and ground, decreased quite sharply, but after that time the current arose very abruptly and at the end of 8 minutes was approximately 30 times its initial value. With this indication the kenotron test was discontinued and the cable was connected to the regular high-voltage a-c.

test set and it was found that the insulation on phase A broke down at a low impressed a-c. potential.

Tests made again on May 30th, (Fig. 4), produced a series of curves apparently free from abnormal characteristics.

RECOGNITION OF APPARENT SOLUTION

Referring again particularly to the tests of March 11th, (Fig. 3), and April 22nd, (Fig. 4), it was felt that the sharp inversion of the curves must be indicative of an unsatisfactory condition of the insulation, since the inversion was followed by an actual breakdown of the particular cable a few days later in the one case, and in the other it was found that the insulation had little, if any, dielectric strength.

Here, then, was a means by which it seemed that it might be possible to determine, through routine tests, the development of faults in cable insulation and to learn of their presence sufficiently early to permit locating them prior to their causing a failure of the cable while in service. The operating results which have been obtained through this method of testing have been most interesting as may be seen from the following test data for other feeders of the 6000-volt system as shown in Figs. 5, 6, 7, 8 and 9.

ADDITIONAL DATA AND OBSERVATIONS

The curves of Figs. 5 and 6 for feeder 109 show quite clearly the progressive nature of the development of a fault, even though the cable was retained in active service and there were no indications, in its operation, of the situation which was impending.

Beginning with the tests for May 5th, 1922, (Fig. 5), the curves for the successive tests indicate more and more the predominance of the leakage current through the insulation, as disclosed by the absence of any marked decrease in the magnitude of the current. This represents the condition where the leakage current of the condenser becomes larger and larger in comparison with the charging currents. Finally, with the test of July 24th, (Fig. 6), the cable was found to be defective. The flatness of the curves, from the test following repairs to the cable, appeared to indicate that the feeder was not yet in really good condition.

The curves of Fig. 7 for feeder 116 show that two impending failures were detected before their occurrences in service. The tests of June 1st and 15th, (Fig. 7), brought to light conditions in the paper insulation such that complete breakdown occurred at 7500-volts on the a-c. test set. The tests of June 26th showed the cable to be in much better condition, following the elimination of the faults located earlier, as indicated by the decrease of current with elapsed time when compared with the slight decrease, or even marked rise, detected in the tests of June 1st and 15th.

The curves of Figs. 8 and 9 for feeder 122 show quite clearly the progressive deterioration of cable insulating materials, as well as the wide differences that may develop in the characteristics of the insulation of the different conductors in a cable. Curve B in the tests of September 22nd and October 6th, (Fig. 8), shows quite clearly, both by the magnitude and form, that the condition of the insulation of that conductor is radically different from that of the other two.

During the year 1922 twelve 6000-volt feeders have been subjected to a routine test by the kenotron at regular intervals of about two weeks. Whenever the test data indicated that the current had a persistent tendency to increase, the cable has been subjected to a high-voltage a-c. test after the completion of the kenotron test. In some twenty instances it has been found that the insulation failed at from 2000 to 7500 volts under a-c. potential. In a few instances the tabular data have indicated a rise in the current value but the

FIG. 9—CURRENT-TIME CURVES

At 9000-volts electrification by kenotron feeder 122; operating voltage 6.0 kv.; $\frac{5 \times 5 \text{ in.}}{32}$ impregnated paper insulation; $3 \times 250,000 = \text{cir. mil.}$ conductors; feeder length 13,234 ft.

incipient fault had not developed sufficiently to cause the cable to fail when placed under a-c. test.

During 1922, by using this method of test, some twenty impending failures have been detected before their actual occurrence, with the net operating result that in only one case has a feeder actually failed while in service. This one instance was undoubtedly due to the fact that it was necessary to discontinue the routine kenotron tests temporarily. The failure occurred during the time the tests were not being made.

Examination of a considerable number of faults which have been predetermined by the kenotron has not disclosed any evidence of over-stressing of the insulating material. The several faults which have been detected to date have had legitimate mechanical explanations, as for example, cracked lead, lead worn through where

the cable has come in contact with the edge of the duct, wrinkled insulating paper or non-uniformity in the construction of splices.

In addition to the investigation which has been carried out on the 6000-volt feeder system some work has also been done in the application of this proposed test method to 13,200-volt, three-phase cables. While the volume of data, which has been obtained to date from these latter tests, is not as extensive as for the tests on the 6000-volt feeders, the resulting current-time curves, (Fig. 10), have not differed materially in shape from those under discussion. Indications are, therefore, that this method of test is directly applicable

desirable and even necessary for some cables. Also, since the shape of the current-time curves is indicative of the condition of the insulation, as has been shown, it is evident that any refinements possible in obtaining accurate test values will be of aid in detecting an impending fault at an earlier stage of its development than is now possible.

CONCLUSION

The material which has been presented leads to the conclusion that the method of testing here outlined provides a means by which it is feasible to determine the operating condition of paper insulation on high-voltage alternating-current transmission cables. It will also be readily seen that this scheme of testing conforms with the desired characteristics of a routine test method which were previously outlined.

Since the major part of this investigation has been carried out on cables which were known to have been manufactured prior to the production of the present day low-dielectric-loss, high-efficiency cable it is believed that a large amount of supplemental information should be obtained.

In the following there are listed a number of points which should be investigated further. They readily arrange themselves in two divisions, viz. practical and theoretical.

PRACTICAL PROBLEMS

1. Determine characteristic current-time curves for high-efficiency cable.
2. Make mechanical study of faults detected by kenotron.
3. Determine feasibility of extending use of kenotron to actual development of fault, without recourse to alternating-current test sets.
4. Ascertain necessity for more sensitive indication of impending failure than indicated by inversion of current-time curves.
5. Determine what, if any, necessity exists for a source of energy for the operation of the kenotron, independent of the station bus supply.

THEORETICAL PROBLEMS

1. Ascertain what, if any, modifications of shape or magnitude, of the current-time curves results from changes in the rate of electrification.
2. What, if any, modification of the current-time curves results from electrifying cables to different ultimate potentials?
3. Determine what modification of the current-time curves results because of different operating temperatures of the cables.
4. Make comprehensive study of wave shape of the current and voltage as supplied by the kenotron under test conditions.
5. What relation, if any, exists between milliamperes per unit of length and condition of cable insulation?

FIG. 10—CURRENT-TIME CURVES

At 15,000-volts electrification by kenotron feeder 345; operating voltage 13.2 kv.; $\frac{7 \times 7 \text{ in.}}{32}$ impregnated paper insulation; $3 \times 250,000 = \text{cir. mil.}$ conductors; feeder length 12,924 ft.

to cables operating at nominal pressures other than 6000-volts.

However, due to the fact that the total current from the kenotron into the cable consists of three components, viz. capacity current, absorption current, and leakage current, and since these vary in magnitude according to the length and condition of insulation of the cable a wide variation in the amount of current to be measured when testing different classes of cables may be expected to occur. Accordingly, refinements in the method and apparatus used for reading the current values may be

6. Determine significance and effect of flashover of the protective sphere gaps, provided on kenotron sets, upon this method of testing.

It is believed the results of investigations now in progress, along some of the lines indicated, will prove of great value.

The assistance that has been received, in the preparation of this paper, from Dr. Steinmetz, Mr. J. L. R. Hayden and Mr. E. E. F. Creighton, of the General Electric Company, and Mr. H. P. Liversidge, Assistant Chief Engineer of The Philadelphia Electric Company, is gratefully acknowledged. We also wish to express our appreciation of the efforts of those in the Station Operating Department and Laboratory Division of The Philadelphia Electric Company who assisted in obtaining the information desired.

Discussion

J. L. R. Hayden: The great value of Messrs. Phelps and Tanzer's paper is its method of indicating the gradual deterioration of a cable insulation. This makes it possible to determine the approach of a failure sufficiently, so that the cable can be broken down out of service by high-potential test, and repaired before it gives trouble in service.

There is probably a slow deterioration of cable insulation while in operation. It is a serious matter to have a cable fail in service. Therefore cables are sometimes given an a-c. high-potential test at regular intervals, so that, if deteriorated, they break down in test rather than in service. But the high test voltage, especially when applied for some time, rapidly deteriorates the cable insulations, so that such periodic high-potential testing may materially reduce the life of the cable, without guarding against a break down in service. The cable may fail under normal voltage, shortly after it was tested, if the deterioration occurring under the high-voltage test has almost reached the failure point, and then is completed to the failure point by the succeeding normal voltage.

The method of testing described by Messrs. Phelps and Tanzer offers the advantage of not deteriorating the cable by exposure to abnormal voltage.

The evidence is continuously becoming more conclusive, that electric failure of solid insulation, especially compound insulation as in a cable, is not a puncture by electric overstress by the voltage, but is of the nature of a gradual deterioration by the combined action of voltage, time and temperature. Therefore a judgment on the progress of the deterioration should be made possible by methods of test showing the internal condition of the insulation. This is the case with d-c. tests, but not with a-c. tests. The alternating current taken by the cable under test is the charge on the metal terminals of the cable as condenser, and does not enter or pass through the insulation thus showing nothing about it. The voltage merely shows why the insulation fails, and then destroys its evidence.

The only feature which has a bearing on the insulation, in the a-c. test, is the power factor, which indicates the losses in the insulation. The power factor therefore is justly considered as an important feature, and low power factor specified. While low power factor is valuable and desirable as meaning low losses and therefore lower temperature, it may be questioned whether for instance, a cable with a somewhat higher power factor, but a power factor which does not vary much with voltage, time, temperature, etc., may not give a better life than a cable in which the power factor greatly varies with voltage, time and temperature.

In the d-c. test, the final value of the current is that which is conducted through the total resistance of the insulation, and

depends on the latter. Therefore it has a slow transient current, which is the current that passes a few seconds after the initial rush of condenser charging current has ceased. This continues to decrease gradually for several minutes. It is a current which passes into the insulation, therefore passes through some of the resistance, and forms internal electric charges within the insulation. It depends on the specific capacities and the resistivities of the different parts of the insulation, and its study should therefore afford information on what goes on inside of the insulation.

D. W. Roper: According to the textbooks, the equation of the curve shown by these authors is as follows:

$$i = \delta_0 + \delta_1 e^{-ct} \quad (1)$$

That equation, with the half transposition, and taking the logarithms, comes out in this form:

$$\log_e \frac{1}{i - \delta_0} = ct + \log_e 1/\delta_1 \quad (2)$$

This equation, you will note, is in the form:

$$y = mx + b,$$

so that it should be a straight line. However, when we take the readings on an underground transmission line and plot them and analyze them, it was discovered by one of my assistants, Mr. Halperin, that instead of getting one straight line, you get two straight lines. The curve found when plotting the points for the second equation seemed to be a straight steep line followed by a curved line in about one minute and finally a less-steep straight line. If you take and work backwards from the first part of the curve and extend it in order to see what the curve would be, if the curve followed the equation for a straight line, then you find that the current goes down to a minimum in about one minute. Or, if you follow the third part curve back to the vertical axis, the initial current reading would be only about one-half of what you actually get; so that apparently the equation as given in the text books needs some revision.

We have endeavored to carry out one of these suggestions of Messrs. Phelps and Tanzer in applying this method of analysis to the modern high-efficiency cables, having a low dielectric loss; but unfortunately, we do not have in these cables, up to the present time, any dielectric loss failures; and it was failures of that particular kind which were discovered in advance and eliminated in Philadelphia.

We have taken quite a few readings and made a number of analyses of tests on these high-efficiency cables, and also on some of the rosin oil cables, which showed very much the same shape of curve; but up to the present time we have not been able to secure practical results from the analysis, but it is interesting to us, at least, to know the peculiar shape of the curve we get upon analysis.

Messrs. Phelps and Tanzer in their paper mentioned that the cables which they tested showed a maximum ratio of 405 to 1, between the initial reading, and the final reading. On some of our 33-kv. cables, we found that the pressure was as high as 150, the current ranging from fifteen milliamperes for the initial reading to 1/10 milli-ampere for the final reading, also, in some of the tests we noticed some interesting differences between the leakage through the cambric insulation and through the impregnated paper insulation.

We have made a number of tests on a 15-mile 33-kv. line, with 19/64 paper around each conductor, and 7/64 belt; and for the test lead between the positive side and the transmission line, we had about 400 ft. of cambric insulated conductor, with about twice the thickness of insulation between the copper and the lead. In making observations on this combination of 400 ft. of cambric cable and the 15-mile line, we find the losses in the paper cable are approximately three-fifths of the total leakage, while there was about 40 per cent of the leakage in the 400 ft. of cambric insulation in the test lead.

Charles P. Steinmetz: Messrs. Phelps and Tanzer's paper shows that from the study of the slow cable transient the deterioration of the insulation can be estimated and its failure thereby anticipated. This is rational, as this slow transient depends on the internal conditions of the insulation. It is a true electrical transient, and of special interest by its long duration, often many minutes, while the external transient of charging the condenser terminals over an inductive supply circuit, usually vanishes within a fraction of a second.

This slow cable transient (the so-called soaking in of the charge, etc.) does not exist if the insulation is perfectly homogeneous; but if the insulation consists of n dielectrics of different specific capacities and resistivities, a slow transient of $(n - 1)$ terms appears.

To illustrate the nature of this transient, let us consider a cable as condenser, in which the dielectric consists of layers of two materials of different specific capacities and different resistivities (paper and rosin oil for instance).

The voltage impressed upon the condenser produces an electrostatic flux between the condenser terminals. A line of electrostatic flux must either return into itself, or terminate in an electrostatic charge. At the first moment of the impressed voltage there can be no internal charges in the dielectric, since there was no time to conduct them through the high resistance of the dielectric. Thus in the first moment, the electrostatic flux density is the same in both dielectrics, and the voltage is distributed between the two dielectrics by their specific capacity, that is, the voltage gradients in the two dielectrics are inversely proportional to the specific capacities.

Due to the finite (though extremely low) conductivity of the dielectric, a current is conducted, or leaks, through the dielectric, and the current density of this current in the two dielectrics is proportional to their respective conductivities, and to their voltage gradients, which latter in the initial moment of the phenomenon depend on the specific capacities. Unless then the resistivities of the two dielectrics happen to be exactly proportional to their specific capacities, the current densities in the two component dielectrics must be different. This means that at every boundary between the two dielectrics a change of current density occurs, and more current flows towards the boundary from the one side, than leaves it on the other side, and consequently, an electrostatic charge builds up at the boundary between the two dielectrics, due to the difference between the two current densities on the two sides of the boundary. This electrostatic charge lowers the voltage gradient and thus the current density in the dielectric of higher current density, and raises it in the dielectric of lower current density, until the current densities in both component dielectrics have become equal and any further building up of internal charge ceases.

The final condition thus is that of uniform current density in both component dielectrics, so that the voltage gradients are proportional to the respective resistivities of the two dielectrics.

Thus in a condenser with a compound dielectric, like a cable, after initial electrification by the rapid external charging transient, an internal voltage adjustment occurs, from the initial voltage distribution corresponding to the specific capacities, to the final voltage distribution corresponding to the respective resistivities of the two dielectrics, with a change from uniform electrostatic flux density and non-uniform current density, to uniform current density and ununiform flux densities terminating at internal electrostatic charges at all the boundaries between the two dielectrics. As the internal static charges have to be conducted through the high resistance of the dielectric, this occurs by a very slow transient, of a duration usually many thousand times greater than the external charging transient.

In the final condition, the stored energy of the condenser is greater than in its initial condition, and its capacity therefore higher.

It can be shown that of the energy of this slow internal transient, half is converted into heat in the resistance of the dielectric, the other half stored as electrostatic energy of the internal charges which after discharge partly appears at the terminals as "residual charge."

Numerous other interesting conclusions follow, for instance that the $i^2 r$ loss in the cable dielectric with alternating current may be many times greater than with direct current, and this additional $i^2 r$ loss is independent of the frequency. The difference between the effective resistance of a cable, measured with alternating current, and the d-c. resistance, is not all dielectric hysteresis, but partly at least true resistance, etc.

As seen, this slow transient gives some information on the individual component dielectrics of such a compound structure as a cable, and in view of its importance in estimating cable deterioration, it may be of interest to give in a later paper the equations of it and thus its relation to the resistivities, capacities, etc. of the different component dielectrics.

G. B. Shanklin: Messrs. Phelps and Tanzer have developed a method of test based on sound principles with which it is possible to discover cable faults during their incipient stage, thereby filling a long felt and urgent need in underground transmission. They claim only that this method of test has worked out successfully on comparatively low-voltage lines (6000 volts) of the old rosin-oil type cable and offer no predictions as to its future usefulness on lines of other and higher voltages.

Considering the principles upon which their method is based, there is no reason why it should not be just as successful on longer, higher-voltage lines of the new type cable. It is a question of obtaining data to prove this point and such work, I understand, is now under way.

The leakage current through a fault during its incipient stage is extremely small, even smaller than the leakage through the rest of the total cable length. Its detection is, therefore, very difficult and the success Messrs. Phelps and Tanzer have had can be attributed to certain factors in their test method:

1st. The use of d-c. voltage, thereby eliminating charging current which would be so high in comparison with leakage current as to completely obscure the results.

2nd. The use of *high* d-c. voltage, which has a tendency to search out and penetrate weak spots, forcing more current through in proportion to leakage current over rest of line. High d-c. voltage also brings the total current within readable values, eliminating the possibility of errors introduced by stray currents, etc. In view of this the curves should be taken at the highest voltage compatible with safety from damage to the sound portion of the line.

3rd. The opportunity of comparing the current vs. time curves of the individual conductors. Single-conductor cable does not offer this opportunity, but perhaps a comparison of the curves taken on cables of the same circuit in adjacent ducts will do just as well.

The above factors all tend to furnish a method of test that is almost unbelievably sensitive, searching out a weak spot perhaps several inches in length in a line miles in length. A careful study of the conductivity of various types of cable faults during their progressive stages of formation is necessary before an exact estimate of the efficacy of this method of test can be made. Such a study will involve serious difficulties. The study would, obviously, have to be made in the laboratory on short lengths, for it is impossible to locate faults on long lines during their initial stages of development, without first reducing them by burning, thereby destroying the desired evidence. In laboratory study the faults would have to be artificially formed and might not represent the same type as those formed in service. When the laboratory and field experiences are combined we may, in time, hope to see this method of test reach its full development.

Public Address Systems

BY I. W. GREEN

Eng. Dept., Western Elec. Co., Inc.

THIS paper aims to present the problems encountered in the development of electrical systems for amplifying the voices of public speakers and music; and to describe the equipment as brought to a commercial state and now in use in the United States and various other countries.

The two main requirements of a successful public address or loud speaking system are, first, that it shall reproduce the sounds, such as speech or music, faithfully; and second, that this faithful reproduction shall be loud enough and sufficiently well distributed, for all of the audience to hear it comfortably. Most of the development work has been directed toward obtaining these two results under the various conditions which surround the operation of these systems.

The faithful and natural reproduction of sound depends upon many factors, of which the following are some of the more important: The acoustics of the space in which the sound originates, the characteristic of the loud speaking system itself and the acoustics of the space in which the sound is reproduced. Where the sound is picked up and reproduced in the same space, as is the case when the speaker is using one of these systems to address a large audience locally, there is a reaction between the horns and the transmitter or pick-up mechanism which is controlled by the acoustic conditions under which the system is operated.

ACOUSTICS OF THE SPACE

In connection with the acoustics of the space in which the sound originates, or in which it is reproduced, four factors stand out. These concern the effects of reverberation, of echo, of resonance, and of diffraction. In the specific cases where the sound is reproduced in the same space or room in which it originates, another effect is encountered, which has generally been termed "singing," and is evidenced if sufficiently great by the emission of a continuous note from the equipment.

Reverberation is caused by reflection and is evidenced by the persistence of the sound after its source has ceased emitting. When the reverberation in the space in which the initial sound is being picked up is sufficient to cause one sound to hang over and become mingled with succeeding sounds, in other words, so that the sound from one syllable interferes with that of the succeeding syllable, it is practically impossible to improve the acoustic conditions solely by the use of the public address system. In such a case, the first procedure is to place material which absorbs sound in the space. The purpose of this absorbing material is to lower the time required for the sound to die away after the source ceases to emit. The amount which any

given material lowers the time of reverberation depends not only upon the amount of material introduced, but also upon its disposition within the space.

The term "echo" applies to a similar phenomenon, but is generally used where there is sufficient time lag between the reflected sound and that originally emitted, so that two distinct impressions reach the ear.¹

The troubles encountered from echoes usually occur only in large buildings or large open spaces surrounded by buildings, trees, or other obstacles and are generally associated with interferences with the reproduced sound rather than with the original sound. There are cases, however, particularly in auditoriums, where some of the walls or ceiling are large curved surfaces, in which case localized echoes may result. The speaker's voice or extraneous sounds from the audience may be reflected from one or more of these surfaces to focus spots where the volume of sound is consequently abnormally great. It is important, therefore, that the transmitter which is picking up the sound shall not be located at one of these spots. These points of localized echo are particularly troublesome also when they occur in the space occupied by the audience. Under these conditions not only is the sound intensity too great, but the character of the sound is altered and very often badly confused. The avoidance of such difficulties is a matter of test and the proper arrangement of the reproducing mechanism, as will be seen later in some detail.

The effect of resonance seldom occurs in connection with the amplified and reproduced sound, inasmuch as the spaces dealt with are large and their natural frequencies are too low to be troublesome. Resonance usually becomes of importance in connection with mounting the pick-up apparatus or transmitter. It generally results from attempts to conceal the transmitter by placing it in some form of small enclosure. The best form of housing from an acoustic standpoint consists of a screen cover which protects the instrument from being struck or injured but in no way affects the sound reaching it.

Resonance produces a distortion which it has been customary to consider as of two varieties. First, there is an unequal amplification of sounds of various frequencies and second, there is the introduction of transients. These transients occur whenever the sound changes but are most easily recognized audibly by their continuation after the source has ceased emitting. They also have frequency characteristics which depend not only on the sound which started them but also upon the character of the resonant portion of the system.

The troubles introduced by diffraction are seldom of

1. Collected Papers on Acoustics, Wallace Clement Sabine, Harvard University Press, 1922.

very great importance except where the sound is reflected from regularly spaced reflectors or passed through regularly spaced openings. Quite serious diffraction troubles have been encountered when operating a loud speaker in a large field, surrounded by an open work board fence, the trouble being evidenced by very distinct areas, particularly at the outskirts of the audience where the sounds were badly distorted.

The difficulties encountered as a result of "singing" form one of the most troublesome problems connected with the actual operation of these systems. When a portion of the sound emitted by the projectors reaches the transmitter with sufficient intensity, that its reproduction is as great as the originally emitted sound from the projectors, and with such phase relation that it tends to aid the original sound, the system will emit a continuous note. Moreover, when the portion of the sound from the projectors which reaches the transmitter is not sufficient to cause a continuous note, it may be sufficient to cause considerable distortion of the speech or music. In excessively reverberant halls these conditions are often fulfilled when the actual amplification is so small that the people at the distant points are scarcely able to hear the speaker. In all cases in our experience the difficulty has been sufficiently overcome by properly placing the transmitter with respect to the projectors. The situation is very much helped by the presence of the audience, which adds considerably to the acoustic damping of the room.

It will be seen, therefore, that the acoustic conditions of the space in which loud speakers are used are of considerable importance.

CHARACTERISTICS OF THE SYSTEM

The first requirement of the system itself is that it shall reproduce speech or music faithfully. A system is said to do this, or in other words, its quality is called perfect, when the reproduced sound contains all of the frequencies, but no others, contained in the original sound striking the "pick-up" mechanism, and when these frequencies have the same relative intensities that they had in the original.

An imperfect or distorting system is one which fails to fulfill this requirement. There are two main types of distortion which had to be considered; the first being the unequal amplification of the system for the various frequencies constituting the sound and the second being the introduction of frequencies not present in the original sound. For simplicity of discussion, this last class will be divided in three parts, namely: the effect of transients, the effect of asymmetric distortion and the effect of disturbing noises.

The effect of transients has already been mentioned in connection with acoustics and they, of course, produce the same type of distortion whether they occur in the acoustic or the electrical system. Transients occur whenever the sound changes either in pitch or intensity, and are introduced at the beginning and ending of each

speech sound. This modification of the characteristics of the speech sounds acts to lower the intelligibility. It probably causes more trouble in speech transmission than the fact that the sound continues after the source ceases.

Asymmetric distortion affects one half of the wave differently from its other half. This causes the introduction of frequencies which, in some cases, produce very serious disturbances in the transmission of music and speech. The most noticeable troubles are from the formation of sum and difference tones.² Such tones are likely to give rise to dissonances with the other sounds occurring in the music. In the case of speech asymmetric distortion manifests itself by a lower intelligibility.

The effect of foreign noises sometimes encountered is twofold. First, they influence the ability of the listener to hear the characteristic speech sounds and hence tend to lower the intelligibility. Secondly, the constant attempt of the hearer to sort out the speech sounds or music through the disturbing noises tires him appreciably. In order that this strain shall be inappreciable, it is desirable that the sound delivered by the system shall be at a power level at least 10,000 times that of the noise.

The second general requirement which is placed on a successful system is that it shall deliver its faithful reproduction loud enough for all the audience to hear it comfortably and enough above noise for good intelligibility. In this connection there have arisen one or two interesting points bearing on the psychology of hearing. One of the most striking of these is concerned with the coordination between hearing and seeing. Although the projectors are usually mounted twenty or more feet above the speaker's head, and in some exceptional cases, slightly to one side of him, the majority of the audience is conscious of only one source of sound, and that appears to be the speaker himself.

This phenomenon is so marked that in several cases the question has been raised in the minds of the listeners as to whether the system was functioning. They could only be convinced that it was by having it shut down for a few seconds when their inability to hear made them realize how successfully the system could operate.

Another of these psychological phenomena deals with the apparent distortion of the voice when its intensity at the ears of the listener is too great or too small. If the speaker is talking in a normal conversational tone, his voice contains a larger percentage of low frequencies than is the case when he is raising his voice to a considerable volume. If the loud speaker so amplifies this voice that it reaches the audience with such volume that their instinct tells them that the speaker should be shouting, the system appears to make his voice sound quite heavy and somewhat

2. Origin of Combination Tones in Microphone-Telephone Circuits. E. Waetzmann, *Annalen der Physik*, Vol. 42, 1913.

unnatural. It has been found necessary, therefore, to so regulate the amount of amplification that the people at the furthest portion of the hall can hear comfortably and the volume of sound should not be permitted to become any louder than necessary to meet this condition. On the other hand, if the volume is insufficiently loud, certain of the weaker speech sounds are entirely lost, and it becomes difficult to understand.³

SOLUTION OF THE PROBLEM

With these considerations in mind it may be interesting to take a brief survey of the whole problem and the method by which the solution was reached. Two

FIG. 1—1-CONDENSER TRANSMITTER WITH ASSOCIATED AMPLIFIER
2-CARBON TRANSMITTER WITHOUT AMPLIFIER

general methods of attack were considered. The first was to attempt to make each unit of the system faithfully reproduce its input, while the second was to make any distortions of one part of the system, cancel those of another portion, so that the complete system would operate satisfactorily. In either case, it was desirable to keep each unit free from asymmetric distortion, as this type of distortion cannot be easily compensated for.

While it would probably have been simpler to follow the second line of attack, the greatly increased flexibility of a system in which each part is correct in itself was of sufficient value to cause the attempt to be made that way. When it is realized that these systems, to be commercially successful, must be capable of operating for various sized audiences, ranging possibly from one thousand to several hundred thousand, that they must be used in connection with long distance telephone lines, as well as with either radio broadcasting or receiving stations, the desire for flexibility can be understood.⁴

As a result of attempting the development in the manner already described, there has resulted a system which involves four functional units; a "pick-up" mechanism or transmitter unit, a preliminary amplifier unit, commonly called the speech input equipment, a second amplifier unit commonly called the power amplifier, and a receiver-projector unit for transform-

ing the amplified currents back into sound, and properly distributing it throughout the space to be covered.

It may be interesting at this place to determine how successfully these various units and the system as a whole fulfill the requirements of equal sensitivity to all frequencies within the important speech or music range. Fig. 1 shows the relative sensitiveness of the transmitter as a function of frequency. The ordinates are proportional to the logarithm of the power delivered for constant sound pressure at the diaphragm and the abscissa to the logarithm of the frequencies employed. The lower of the two figures refers to the condenser transmitter with its associated input amplifier.⁵ The upper refers to the push-pull carbon-type transmitter. These transmitters will be described in detail later.

Fig. 2 shows a similar curve for the complete amplifier system, comprising a three-stage speech input amplifier, and a power stage capable of delivering approximately 40 watts of speech frequency electrical power without distortion. In connection with these amplifiers a sharp distinction should be made between their gain rating, or amplification, and their overload or power rating. Gain measures the power amplification which can be obtained provided the input is small enough so that the equipment at the output end is not overloaded. Overload or power rating refers to the maximum power which can be supplied by the amplifier without causing distortion of the currents being amplified. Although the power rating of power equipment is usually determined by the heat which can be dissipated, a marked distortion of wave form takes place when the iron in any

FIG. 2—PUBLIC ADDRESS SYSTEM AMPLIFIERS

of the apparatus is worked beyond the straight line portion of the magnetization curve. In the case of amplifiers, the maximum power obtainable is limited by the power output at which distortion occurs rather than by the heat which can be dissipated.

Fig. 3 shows a chart for the characteristics of the complete system, including the carbon transmitter, the speech input and power amplifiers and the receiver projector unit.

In connection with the requirements for equal

amplification of all frequencies, it is interesting to note that a system, which does not fail to reproduce equally all frequencies in the speech range by more than a ratio of 10 to 1 in reproduced power, is indistinguishable, from a perfect system or from the speaker, himself. It seems probable that this effect is, in some way, connected with variations in the frequency sensitiveness curve of normal ears. Normal ears show a sensitiveness variation with frequency as great as 10 to 1 and the frequencies of maximum sensitiveness vary materially from one individual to another.⁶

FIG. 3—COMPLETE PUBLIC ADDRESS SYSTEM WITH CARBON TRANSMITTER

It has been found that in order to transmit speech with entire satisfaction for loud speaker purposes, that is, sufficiently well so that the audience is not aware of the contribution of the mechanical equipment, it is necessary for the system to operate with essentially uniform amplification over a range of frequencies from 200 to 4000 cycles. While there are, in speech, frequencies slightly outside of this range, the loss in naturalness and intelligibility by the system's failure to reproduce them, is slight.⁷

While no such frequency range is required for intelligibility only, it has been found that systems not covering substantially this frequency range, sound unnatural. When the lower frequencies are missing, the reproduction sounds "tinny." When the higher frequencies are missing it sounds heavy and muffled. The requirements for thoroughly natural reproduction of music are probably more severe, particularly in the low-frequency region, than are the similar requirements for speech, but, at the present time, complete data are not available to indicate the contribution of these frequencies to naturalness.

In connection with the flexibility of the system, it is interesting to note that the speech input equipment has been designed to raise the power delivered by the transmitter to such an extent that it is sufficient for long distance telephone transmission or for the operation of a radio transmitting set. The power amplifier is

7. The Nature of Speech and its Interpretation. Harvey Fletcher, *Journal of the Franklin Institute*, Vol. 193, No. 6, June 1922.

designed to receive power at approximately this level and deliver it to the projector units sufficiently amplified to operate them satisfactorily.

FUTURE DEVELOPMENT

In viewing the loud speaker field from the point of view of future development there are two lines of attack along which work is being done, and which give promise of success. These are the improvements in frequency characteristics and increase in the range of loudness which the system can accommodate satisfactorily.

The improvement to be expected from a more uniform frequency characteristic is mainly an increase in naturalness, especially where music is being reproduced. A slight increase in intelligibility may be hoped for, although this factor is of little importance, as the present system is satisfactory in this respect.

The other improvement mentioned, namely, the volume range, is probably the more difficult, but is necessary before music can be reproduced in a perfect manner. Rough experimental data indicate that the loudness in an orchestra selection may vary from one part of the selection to another by a ratio as great as 50,000 to 1. While the present equipment does not operate with entire satisfaction over this range of loudness, it has been found relatively easy to obtain good results by manual adjustment of the amplification during the rendering of the selection. If the gain is

FIG. 4

varied in small enough steps, the change is not noticeable to the listeners.

An increase in the loudness range would render the manual adjustment unnecessary and would make the reproduction a faithful duplicate of the music as actually played.

TECHNICAL DESCRIPTION OF THE SYSTEM

The foregoing discussion having described the requirements which must be met in order that the public address

system shall successfully transmit speech and music, the system in its commercial form will now be described. In order to make clear the arrangement of the equipment, a typical installation is shown in Fig. 4, this being an installation where the audience and speaker are in the open air, and where no connection is made with the long distance lines. It might be well to state here that with the equipment shown an audience of 700,000 can be adequately covered.

Some of the sound leaving the speaker's mouth is picked up by the transmitter, on a reading-desk type of pedestal, which is normally mounted at the front of the platform.

FIG. 5

The feeble currents from this transmitter are led by carefully shielded leads to the amplifiers in the control room, which is usually located directly beneath or to one side of the speaker's stand. A floor space of not more than 125 square feet is required for this room, even in the case where it is desirable to transmit phonograph music to the audience between speeches.

The amplifier and power supply equipment is shown on the two panels in the center of the control room. The amplified speech currents are led from these amplifiers to the receiver projector units, which, in this case, are arranged on the super-structure above the speaker's platform. This position is most desirable, as the illusion produced is such that the voice appears to come from the speaker rather than from the projectors, a factor, the importance of which has already been mentioned. Moreover in this position the acoustic coupling between the transmitter and the projector is a minimum, permitting the operation of the system at a satisfactory degree of amplification with an ample margin below the point where singing troubles are encountered.

A public address equipment, similar to that just described, but with a somewhat lower power output, has been developed for use at the smaller open air meetings, and in all but the largest indoor auditoriums. Fig. No. 5 shows one of these equipments, mounted on an automobile truck, which has been employed at a number of points in the eastern part of the United States. This smaller system has characteristics equally

as good as the larger system in regard to faithful reproduction of speech and music, with a power output in the order of one-tenth as great. An audience of 50,000 can be adequately covered at an outdoor meeting with this system.

Fig. No. 6 is a schematic arrangement of the equipment at an installation of the type shown in Fig. 4. At the extreme left are the transmitters where the sound waves are picked up. The output from these transmitters is taken to a switching panel where means are provided for cutting in the various transmitters. From this panel the transmitter currents are taken to the transmitter amplifier, which is capable of amplifying them to a power level suitable for input to the power amplifier, or for connection to the long distance lines, in those cases where the speeches are transmitted to distant audiences. It is also suitable where connection is to be made to a radio station for broadcasting the speeches. The power amplifier is shown just to the right of the transmitter amplifier. Below it is indicated the power supply equipment by which the commercial power is converted to a form suitable for the vacuum tubes in both amplifiers. The output from the power amplifier is taken through a panel where switches and a multi-step auto-transformer are provided for the regulation of several projector circuits. Just above this panel is an indicating instrument, known as the volume indicator, provided in order that the operator may know what volume output is being delivered to the projectors.

FIG. 6

The projectors, at the extreme right of the figure, consist of the motor or receiver unit transforming the speech currents into sound waves, and a horn to provide the proper distribution of the sound.

It is interesting to note the power amplification which is obtained in the larger of the two systems from the transmitter to the projectors. Referring to Fig. No. 6, a chart will be seen which indicates the power levels through the system drawn to a scale based on miles of standard telephone cable, our usual reference unit. The output of the high quality transmitter is

of the order of 65 miles below zero level, this latter being the output from a standard telephone set connected to a common battery central office by a line of zero resistance. Expressed in watts the output of this transmitter under average conditions of use with the public address system is of the order of 10^{-8} watts. Incidentally, this is of the same order as the speech power picked up by the transmitter, or in other words, the transmitter does not amplify the speech power received by it as is the case with the transmitter used for regular telephone service.

This very minute amount of power in passing through the transmitter amplifier may be amplified about 120,000,000 times. Expressed in terms of telephone power levels, this is 17 miles above the zero level previously mentioned, or a few tenths of a watt.

The power amplifier serves to increase this power from a level of 17 miles to about 40 miles, the latter corresponding to about 40 watts. This power is then distributed to the projectors, the amount consumed by each projector, of course, depending upon the number connected.

An idea of what this amount of power at speech frequencies means may be given by the statement that it is sufficient to operate at a volume level slightly above that considered commercial all of the 12,000,000 telephone receivers in use in the Bell system if these were directly connected to the amplifier.

In describing the various pieces of equipment which together make up the system, we will follow the order in which the power is carried through the system from the transmitter to the receiver-projector units where the amplified sound waves are propagated.

TRANSMITTERS

In the early work on the public address system, an air-damped, stretched diaphragm condenser transmitter was employed, having a thin steel diaphragm about $2\frac{1}{4}$ inches in diameter, constituting one plate of the condenser. The other plate was a rigid disk, the dielectric being an air film $1/1000$ of an inch in thickness. Due to the stretching of the diaphragm and the stiffness of the air film, the diaphragm of this transmitter had a natural period of approximately 8000 cycles per second which is well above the important frequencies in the voice range. This high natural period, in conjunction with the damping due to the thin film of air, resulted in a transmitter of very high quality of reproduction. However, its extremely small capacity (in the order of 400 micro-microfarads) made it necessary to use leads of very low capacity between the transmitter and the first amplifier, and due to the high impedance of the transmitter and its associated input circuit to voice frequency currents, these leads were very susceptible to electrostatic and electromagnetic induction. It was necessary to limit them to a length of 25 feet, and to provide complete shielding. Moreover the output of this transmitter was less than one

five-thousandth of that of the transmitter now used, and for the early installations of the system, it was necessary to provide a preliminary amplifier beneath or to one side of the speaker's stand in order to keep the transmitter leads short and to provide sufficient power to properly operate the main amplifiers. Work was therefore undertaken to provide a transmitter, having quality practically as good as the condenser transmitter, volume output sufficient to operate the main amplifiers, and not requiring the elaborate precautions as to shielding the leads.

The high quality transmitter which was the result of this development work is of the granular carbon type with two variable resistance elements, one on each side of the diaphragm and is commonly known as a push-pull transmitter. It has nearly the same high quality reproduction characteristics as the condenser transmitter, due to the use of the same stretched diaphragm and air damping structure. It introduces no appreciable distortion over the range of frequencies required for good reproduction of speech, but it must be understood, that this quality was obtained only at

FIG. 7

the sacrifice of sensitiveness, the latter being in the order of $1/1000$ th that of the transmitter used at telephone stations in the Bell system. With the multi-stage vacuum tube amplifiers available this low volume efficiency is not serious and in fact we are using this transmitter for what is known as distant talking, *i. e.*, the speaker may be at a distance of five or six feet from the transmitter. This is, of course, necessary in any transmitter suitable for public address work as it is not possible to greatly limit the movement of the speakers, nor can they be required to use a hand transmitter. It might be well to point out that this sacrifice in volume efficiency in order to gain high quality is possible at the transmitting end of the system, but not at the opposite end where the electrical power is transformed into sound waves and propagated, as the device at this point must be capable of handling large amounts of power with minimum distortion.

Referring to Fig. No. 7 which is a cut-away view of this push-pull high quality carbon transmitter, the granular carbon chambers will be seen. The electrical path through each of these variable resistance elements is from the rear carbon electrode through the carbon granules to a gold-plated area on the diaphragm itself. The resistance of this path is about 100 ohms and as the two buttons are in series for the telephone

currents, the transmitter is designed to work into an impedance of 200 ohms. The double button construction almost completely eliminates the distortion caused by the non-linear nature of the pressure-resistance characteristics of granular carbon.

As this instrument has a practically flat frequency characteristic no collecting horn or mouth piece is used with it as resonance is introduced by such chambers, with accompanying distortion. To insure the insulation of the transmitter from building vibrations, a simple spring suspension has been provided. To protect the transmitter from injury, two types of transmitter mountings have been used, both arranged for the suspension of the transmitter in a screen-enclosed space—the first adapted to take a single transmitter for indoor use only, while the second for outdoor use, mounts two transmitters within a double screen enclosure to prevent any noise effects due to winds. This second type is arranged to attach to a simple pedestal-type of reading desk, which it has been found desirable to provide as there is a slight tendency for the speaker to remain fairly close to the desk. In this connection it is interesting to note that we have found a small rug, so placed as to cover the area which the speaker should occupy during the delivery of his speech, is of great assistance in this regard, as he unconsciously confines himself to the area of this rug. Both of these measures to insure the speaker remaining in proper relation to the transmitter, are supplemented, wherever possible, by an explanation of the system to all the speakers previous to the actual performance.

TRANSMITTER SWITCHING PANEL

Resuming the path of the speech currents through the system, the output from the transmitters is taken to a panel designed to enable the operator to switch quickly from one transmitter to another, as with some public functions, the speeches are made at different points during the ceremonies. This switch is arranged to short-circuit the output of the power amplifier when passing from one transmitter to another, to prevent clicks in the projectors. In certain cases, the equipment is arranged to permit two or more transmitters to be connected to the amplifiers at one time, as is desirable when solo singers and an orchestra are to be picked up in a theatre, with proper adjustment of their respective volumes.

The amplifier equipment has been built in four units which may be grouped as necessary under the various conditions encountered in commercial installations. The proper amplifiers are determined, first, by the source of the voice frequency current to be amplified, that is whether a distant talking or a close talking transmitter is to be used, or whether the speeches are brought in over a telephone line, and secondly, the size of the space in which the amplified sounds are to be delivered to the audience. It was found that four units would provide for all the conditions occurring in

practise, two of these being speech input or transmitter amplifiers with different gains and two being power amplifiers of different power ratings. These units and other equipment used with the system, are made up in panels, of uniform width, in order that the proper equipment for any installation may be assembled on two vertical angle iron racks arranged to be fastened to the control room floor.

SPEECH INPUT AMPLIFIER—FIRST TYPE

The first of the speech input amplifiers is shown schematically in the upper part of Fig. 8. It is a three-stage amplifier. Two potentiometers provide adjustment of the gain over a large range, and switching arrangements allow the output to be connected directly to the input of the power amplifier, when the program is to be transmitted to a local audience; or to be connected, through a transformer of proper impedance, to

FIG. 8

the long distance lines when the program is to be transmitted to a distant audience, or to a radio-broadcasting station. The filaments of the tubes are supplied from a 12-volt storage battery, while the plate circuits obtain direct current at 350 volts from the power supply equipment mentioned later. Arrangements are also provided for using 130 volts instead of 350 volts under certain conditions. The proper grid potentials are obtained by utilizing the drop over a resistance in the filament circuits of the first two tubes, and for the third tube small dry cells furnish the grid potential. The maximum gain with this amplifier is 85 miles, which expressed as a power ratio is 1.2×10^8 . The maximum power output is approximately $3/10$ of a watt. The front and rear views of this amplifier, mounted on the supporting rack, are shown in Fig. 13, where the gain regulating potentiometer, the rheostats for controlling the filament and transmitter currents, the three tube mountings

with protective gratings and the jacks which permit the connection of instruments for determining the current flow in the filament plate and transmitter circuits, will be noted. Great care was taken in the design of this amplifier to obtain as nearly as possible equal amplification of all frequencies in the important voice range. The transformers, and the retardation coils in the plate circuits were chosen with this consideration in mind.

POWER AMPLIFIERS

For practically all of the larger installations the maximum power possible with the system is required and the output from the transmitter-amplifier is taken directly to the high power amplifier. Referring to Fig. 9 it will be seen that this is a four-tube amplifier so connected that but one stage of amplification is obtained.

FIG. 9

Usually alternating current at 12 to 14 volts is used for heating the filaments of these tubes, the latter being connected in what we know as a push-pull arrangement. It will be seen that each side of the push-pull arrangement consists of two power tubes in multiple. It is interesting to note that this push-pull arrangement of the tubes will deliver somewhat more power for equal quality than the same number of tubes connected in the ordinary multiple arrangement, as the tubes may be worked beyond the straight part of their characteristic. The grid potential is chosen to permit the largest variation of current without distortion and is obtained from a group of small flashlight batteries.

The output transformer at the right of the figure is designed to match accurately the impedance of the tubes to that of the number of receiver-projector units which has been found to give the greatest flexibility

under the varying conditions of commercial operation. This amplifier, speaking in telephone terms is worked at a gain of 23 miles, a power amplification ratio of about 200. Its maximum power output is about 40 watts. The plate circuits of the tubes are supplied at a d-c. potential of 750 volts. As has been pointed out previously, this amplifier gives a practically uniform gain for all the important frequencies in the voice range. This high-power amplifier is shown mounted on the supporting rack, in Fig. 13. The apparatus on the rear of the panel is protected with a sheet metal cover and integral with this cover is a disconnecting switch, which, when the cover is removed, cuts off the high potential from all the exposed parts on the set.

For indoor installations where the audience is small the power output given by the high-power amplifier is not required and a medium-power amplifier has been developed for this use. It is arranged to connect directly to the transmitter amplifier and the output is taken to the projectors through the volume control panel. It is worked at a gain of 17 miles or a power amplification ratio of about 33. The maximum output is about 4 watts, or about one-tenth of the power obtainable from the high-power amplifier.

The schematic of this amplifier, is shown in Fig. 9. The input coil is the same as is used in the high-power amplifier. The push-pull connection of the tubes is also used in this amplifier, although but two power tubes are used. The filaments of these tubes are supplied from a 12-volt storage battery while the plate circuits are supplied at 350 volts direct current from a motor generator set which will be described later.

SPEECH INPUT AMPLIFIER—SECOND TYPE

A speaker using the system may read his speech from his home or office and in such cases it is unnecessary to use the push-pull carbon transmitter in the distant-talking manner. For use when this transmitter is spoken into from a distance of a few inches, a second form of speech input amplifier has been made available having a gain of the proper value to supply either of the power amplifiers, or a long distance line if desired. This gain is relatively small as the output of the transmitter when used for close talking is about 10,000 times that when it is used for distant talking.

Fig. 8 shows the schematic of this amplifier which is a single-stage one, employing one tube and having the same over-load characteristic as the first form of speech-input amplifier. A two-way switch permits the connection of the transmitter or an incoming long distance line to the amplifier. To the right of this switch is a potentiometer for regulation of the gain. To the right of the tube is a second two-way switch for connecting the output either to the power amplifier or through an output transformer to an outgoing long distance line. The power supply for the tubes and transmitters, is the same as was described under the first form of speech input amplifier.

The switching means provided on this amplifier allow it to be used in a number of ways. Announcements from a close talking transmitter may be made from the projectors through a power amplifier or may be sent out on the telephone lines to a distant public address system installation or a radio-broadcasting station. In addition to these uses, incoming speech over the long distance lines may be put out on the projectors through the power amplifier or may be sent out on the long distance lines to a distant installation.

VOLUME CONTROL

As discussed heretofore, it is necessary to give the operator control of the volume put out by each projector or group of projectors. The equipment provided for this purpose is mounted on a panel uniform with the others and consists essentially of an auto-transformer connected across the output of the power amplifier with 11 taps multiplied to the contacts of eight dial switches, the arrangement being shown schematically in Fig. 10. Seven of the dials control projector circuits on each of which one or more projectors may be grouped, the eighth dial being reserved for controlling the volume of

FIG. 10

the operator's monitoring projector in the control room. A key is associated with each dial for opening the circuit and a master key is provided for cutting off all of the projectors simultaneously.

The device shown as "Volume Indicator" in this figure consists of a vacuum tube detector bridged across the output terminals of the power amplifier. The rectified current is taken to a sensitive direct-current meter of the moving coil type, the degree of deflection of this meter measuring the output from the power amplifier when connected at a proper place in the circuit. The deflections of the meter therefore serve as a basis for determining the adjustment required on the transmitter-amplifier to give the required output when switching from one transmitter to another or for different speakers.

RECEIVER—PROJECTORS

From the control panel the power is taken to the projectors, each of these consisting of a loud-speaking receiver mechanism to transform the speech-currents into sound waves, and a horn to distribute the sound. The receiver is so designed that it will carry several watts with small distortion. It is shown in Fig. 11 where it will be seen that a light spring-supported iron

armature is mounted between the poles of a permanent magnet and passes through the center of the coils carrying the voice currents. A light connecting link ties one end of this armature to the diaphragm which is of impregnated cloth, corrugated to permit vibrations of large amplitude. A stamped metal cover protects the parts from mechanical injury, and a cast iron case, in which the whole assembly mounts, is provided for protection against moisture.

One of these receivers equipped with the largest projector provided, will carry without serious distortion

FIG. 11

or overheating, power which is about 27 miles above the zero level. With this output, it is possible to project speech a distance of 1000 feet under ordinary weather conditions and this has been done at several installations.

On account of the different conditions encountered in installations three types of horns have been used, shown in Fig. 12. Where it is necessary to project the sound to great distances, a tapering wooden horn is used, of rectangular cross section, 10-1/2 feet long, the

FIG. 12

walls being stiffened to prevent lateral vibration. For most installations these large horns are not required, and two types of fibre horns are used. One of these is straight in the body, with a flaring open end, while the other used in the control room, is bent.

The grouping of projector units on the volume control switches differs with the type of installation. In outdoor performances, the necessity of correcting the volume in certain directions due to varying winds makes it advisable to group adjacent projectors on a single switch. This is not the case with indoor per-

formances, as no wind effects are possible. Instead, symmetrically placed projectors which will always require equal volume are grouped on a single switch.

POWER SUPPLY EQUIPMENT

In order to convert the commercial electric power supply to forms suitable for supplying the filament and plate current for the vacuum tubes in the amplifiers,

FIG. 13

two types of power equipment have been made available. When the installation is of a size requiring the high-power amplifier, a vacuum tube rectifier taking its supply at 110 or 220 volts, 60 cycles, and delivering 750 volts direct current for the plate circuits is employed. A potentiometer arrangement provides a direct-current supply at 350 volts for the speech-input amplifier tubes. Full wave rectification is obtained and a filter consisting of a large series reactance coil

FIG. 14A

and bridged condensers is used to render the direct-current output suitable for this use. Included in the power equipment is a step-down transformer for supplying the filament of the power amplifier. For the larger installations, employing the rectifier, the total power drawn from the commercial supply is 1500 watts.

For installations of a size not requiring the use of the high-power amplifier, a compact motor generator

set is provided consisting of a 350-volt d-c. generator driven by a suitable motor, the total power drawn from the supply mains being about 600 watts. A low-voltage generator for supplying direct current at 12 volts for the operation of the amplifier tubes is incorporated in this motor generator set. A filter is necessary and a reactance coil and a 12-volt storage battery is floated across its output. This supplies the transmitters and

FIG. 14B

the tube filaments. The necessary indicating meters are provided on a meter panel for observing the voltages and currents of all the items of equipment which do not have individual meters associated with them.

OBSERVING SYSTEM

In addition to the monitoring projector provided in the control room for the guidance of the operator, it has been found necessary in all but the simplest instal-

FIG. 15

lations to provide observing stations at various points in the audience. The observers stationed at these points are equipped with portable telephone sets, by which they may immediately communicate with the operator, who is provided with a telephone set consisting of a head receiver and a breast transmitter. The value of these observation stations for regulation of output volume during a program will be apparent.

In the case of an open air performance a variable wind may make it necessary to increase the volume of

certain projectors and decrease the volume of others in order to cover the audience uniformly. Without the observers, the control operator would be unable to take care of these changes.

Considerable preparation is required where the equipment is being used for the first time, in order that the performance of the public address system installation will be of the highest order. Where the acoustic conditions are unfavorable it is necessary to make tests

FIG. 16A

with various arrangements of the projectors, in order to determine the most satisfactory one. It has been found advisable to carry out the entire program previous to the performance in order that the operating force may become familiar with the sequence.

CONCLUSION

The usefulness of such systems is very well illustrated by a few of the results which have actually been ob-

FIG. 16B

tained. Fig. 14 shows a crowd of approximately 125,000 people, every one of whom was able to hear clearly and distinctly all of the words spoken in President Harding's inaugural address in March 1921. This crowd was relatively small, compared with the crowd which could be accommodated by one of the larger type systems. Some insight into the number of people which could be accommodated can be gained from the fact that such a system will cover comfortably a com-

plete circle whose diameter is 2000 feet when the projector units are placed at the center.

One of the largest and most successful uses to which this equipment has been put took place on Armistice Day in 1921 when 20,000 people in San Francisco, 35,000 people at Madison Square Garden, New York City, and approximately 100,000 people at Arlington Cemetery near Washington joined in the impressive ceremonies which took place at the burial of the Un-

FIG. 17B

known Soldier. Figs. 15, 16 and 17 are views at the three cities, during the ceremonies.

Some of the other uses which have been made of the public address system are the Republican and Democratic Conventions prior to the last presidential election, after-dinner speaking in large ballrooms and in halls where speakers have to address large audiences.

FIG. 17A

There is one more application of this type of equipment which is gaining rapidly in its use. This last is the application of the speech input equipment to radio broadcasting. The broadcasting of the opera, Aida, from the Kingsbridge Armory, and of the Philharmonic Concerts from the Great Hall of the College of the City of New York are two of the successful uses where music

and speech were concerned, while broadcasting of the results of the football games from the various distant cities indicate possibilities for the dissemination of interesting information⁸.

The social and economic possibilities of the system are scarcely realized by the public as a whole at the present time, when the method resorted to for reaching large numbers of people is usually the printed word. While this method is effective, it leaves much to be desired in that the personal touch between the man with ideas and the people to receive them is entirely lost. The difficulty for any but those possessing the strongest voices to reach an appreciable number of people at one time has led to a decline in oratory as a means of conveying public messages to large numbers, for it is not always the man with the best ideas or the best ability of presenting them, who is blessed with a powerful voice.

8. Use of Public Address Systems with Telephone Lines.
W. H. Martin and A. B. Clark.

A system such as the one which has just been described enables the speaker, even though his voice be relatively weak, to address at one time and in one gathering, several hundred thousand persons, and if the system be used in connection with long distance telephone lines or radio broadcasting, the number which may be reached is increased almost indefinitely. The value of such a situation can hardly be overrated in times of national emergency or stress, when it is necessary for those in responsible positions in the Government to get their message to the people directly.

The development of the apparatus just described has been the result of the efforts of such a large number of investigators working cooperatively that no attempt has been made to acknowledge their individual contributions.

Discussion

For discussion of this paper see p. 83.

Use of Public Address System with Telephone Lines

BY W. H. MARTIN

and

A. B. CLARK

The combination of the public address system and the telephone line makes it possible for a speaker to address simultaneously audiences located at a number of places. This paper discusses various applications of this combination, states the requirements for the lines, shows the circuit arrangements used and describes some of the important operating features.

A description is given of the system used on Armistice Day, 1921, when large audiences at Arlington, New York and San Francisco joined in the ceremonies attending the Burial of the Unknown Soldier at the National Cemetery at Arlington, Virginia.

The application of the public address system apparatus and methods to radio broadcasting is also briefly discussed.

THE public address system which is described in a paper by I. W. Green and J. P. Maxfield, was developed and first used for the purpose of extending the range of the voice of a speaker addressing an audience. With the aid of this system enormous crowds extending from the speaker's stand to points a thousand feet and more distant have in reality become an audience and have easily understood the speaker whose unaided voice covered only that portion of the crowd within a hundred feet or so from him.

When this system, consisting of a high quality telephone transmitter, distortionless multi-stage vacuum tube amplifiers, powerful loud speaking receivers and projectors, had so shown its capabilities, in reproducing speech sounds, a logical extension of its application was to use it with telephone lines. By connecting the transmitting and receiving elements of the public address system through a suitable telephone line a

system is provided whereby a speaker can address an audience at a distant point. Also with a complete public address system at the point where the speaker is located, connected by lines to receiving elements of the public address system located at one or more distant points, the speaker is enabled to address a large local audience and to be heard simultaneously by audiences at one or more remote points. This last arrangement was first used on Armistice Day, 1921, when audiences at Arlington, New York and San Francisco joined together in the ceremonies attending the burial of the Unknown Soldier at the National Cemetery at Arlington, Virginia.

By means of the public address system, the meeting of this Institute at New York, at which this paper is presented is attended and participated in by Institute members at a meeting in Chicago. This is the first occasion on which complete public address systems installed at meetings in two cities have been connected together by telephone lines so that speakers at each

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 14-17, 1923.

meeting address the local and distant audiences simultaneously.

With the transmitting element of the public address system working into the radio transmitter of a broadcasting station and with the receiving elements of the system connected to the output of the radio receiving sets, a system is provided whereby a number of people can be reached by each radio receiver.

The combination of these wire and radio communication channels with the elements of the public address system is, therefore, without limit in the number of persons who may be reached simultaneously by one speaker. Such combinations may prove extremely serviceable for occasions of nation-wide interest and importance.

The public address system apparatus has been used not only for transmitting speech sounds but also for music, both vocal and instrumental. The paper¹ describing the public address system has pointed out that the requirements for such a system are that for a wide frequency range it be practically distortionless, that is, transmit and reproduce with equal efficiency all frequencies in that range. This requirement must apply likewise to lines which are used with the loud speaker system. It has been found that a circuit which transmits without material distortion the frequency range from about 400 to 2000 cycles, can be used with the public address system to reproduce speech sounds which are fairly understandable under favorable conditions, although sounding unnatural. In general it is important to extend this range at both ends in order to improve the intelligibility of the sounds and increase the naturalness. For vocal and for some types of instrumental music the melody can be reproduced with the above frequency range, but these tones also are lacking in naturalness. Since some of the musical instruments are used to produce tones three and even four octaves below middle C, it is evident that the proper reproduction of music requires a further extension of the lower limit of the transmitted band than does speech. While the fundamentals of the higher musical tones lie in general in the range mentioned above, it is the harmonics in musical tones which distinguish those produced by different instruments and which give what musicians term "brilliance." The true reproduction of many musical selections requires the distortionless transmission of a frequency band of from about 16 cycles to above 5000 cycles. Many musical selections, however, employ only a part of this range and accordingly can be satisfactorily reproduced by systems not transmitting the whole range. Also, even with slight distortion obtained with somewhat narrower ranges, reproductions may be given which are agreeable to many popular audiences.

LINE REQUIREMENTS

In general the same line requirements which make for

1. Green and Maxfield, "Public Address System."

satisfactory transmission of speech over commercial telephone circuits also make for satisfactory transmission when telephone circuits are associated with loud speakers. There is this difference however. The loud speakers tend to make the line distortion much more noticeable and serious. Speech transmitted over a particular telephone line is, in general, more difficult to understand when listening to loud speakers than when listening to telephone receivers.

In commercial telephone service the main requirement is intelligibility while, with the loud speaker, the naturalness of the reproduced speech sounds is very important. People are accustomed to hearing transmission through the air with very little distortion and naturally expect the same results with loud speakers.

The above constitute the reasons why, for transmitting voice currents over telephone lines with loud speakers, it is necessary to pay unusual attention to the electrical characteristics of the lines. Evidently when music is to be transmitted, particularly music of a fairly high grade, it is necessary to place even more severe electrical requirements on the lines.

An analysis of what constitutes the electrical requirements of a telephone line which make for good transmission, particularly when loud speakers are employed, will now be given.

In the first place, as explained above, it is essential that a sufficiently broad frequency range be transmitted. As explained in another paper² it is not sufficient that a telephone circuit transmit sustained alternating currents within a given frequency range. It must also transmit short pulses of alternating currents within the proper frequency range without introducing oscillations of its own or "transient effects." This requires that loaded circuits for loud speaker use have a high cut-off frequency and hence have the frequencies of the predominant natural oscillations high. It has been found that when the cut-off frequency of loaded circuits is about 5000 cycles, good results are secured with loud speakers.

The two types of telephone circuit which best meet the requirements of transmitting a broad band of frequencies, both when sustained and when applied in short pulses, are non-loaded open-wire lines and extra-light loaded cable circuits. These are suitable for transmission over very long distances. For transmission over short distances, say from one point in a city to another point in the same city, non-loaded cable circuits equipped with distortion networks or attenuation equalizers for equalizing the attenuation, give good results.

A good idea of the range of frequencies which can be transmitted over high grade telephone circuits can be secured from Fig. 1, which shows the transmission efficiency at different frequencies for the New York-

2. Clark, Telephone Transmission over Long Cable Circuits, see p. 86.

intermediate points in the circuit will also be kept within proper limits. Long telephone lines are designed with special emphasis on this matter of constant efficiency so that, in general, no special precautions are required when using these circuits in connection with loud speakers.

In another paper,³ the "echo" effects which may occur on long telephone circuits are explained. When setting up two-way circuits for loud speaker use, it is necessary to pay particular attention to effects of this sort. Furthermore, there is another source tending to produce echoes in circuits arranged for two-way use with loud speakers. This is the tendency for the sound delivered from the loud speaker projectors to enter the sensitive transmitter and be returned to the distant end of the circuit as an echo. Owing to the relatively slow velocity of transmission of sound through air the lag in such an echo may be great enough to be serious, although the line is a short one with high transmission velocity. It is, therefore, evident that this coupling through the air between the loud speaker projector and the transmitter must be kept small. If a very sensitive transmitter arranged so that a speaker may stand several feet away from it is employed, this problem becomes even more difficult.

There is one thing more that remains to be considered: the necessity for special operation. When a large number of people are assembled at some point to hear an address delivered at a distant point, it is evident that delay in establishing the connections cannot be tolerated. It is, therefore, necessary to establish such connections ahead of time and it is usually also necessary to set up spare circuits for use in case of failure of the regular circuits. A special operating force is required for checking up the circuits, establishing the connections when required, and making the necessary adjustments.

FIG. 3—ONE-WAY CONNECTION TO POINT IN SAME CITY

Rehearsals are necessary on important occasions to insure proper functioning of the circuits and proper coordination of the handling of the circuits with the programs at different points.

TYPICAL CIRCUIT COMBINATIONS OF PUBLIC ADDRESS SYSTEM AND LINES

Following are a number of typical combinations of the public address system and telephone lines. The combinations by means of which one-way service may be rendered, are given first, following which certain combinations for giving two-way service are discussed.

By one-way service is meant service in which no provision is made for anyone in the distant audience to

talk to the place where the speaker is located. Two-way service provides for speakers at either of two or more points addressing all of the other points. This is similar to the two-way service rendered by regular telephone circuits.

Fig. 3 shows the circuit arrangement which would be used when a speaker at one point in a city, for example, at his office, is to address an audience at another point in the same city. A high quality close talking transmitter T , together with a fixed gain single-stage amplifier A , are provided at the point where the speaker is located. This combination is designed to deliver to the line the same amount of power as a commercial type substation set. Connecting this point with the

FIG. 4—ONE-WAY CONNECTION TO POINT IN DISTANT CITY

point at which the audience is gathered is a non-loaded cable circuit. To correct for the distortion in this cable circuit, an attenuation equalizer E is provided. The apparatus at the point where the audience is located is the equipment of the public address system without the transmitter and its associated amplifier. In Fig. 3, B is the amplifier for delivering sufficient power to the group of loud speaker projectors indicated by R . A volume indicator V associated with the amplifier B is used in maintaining constant the volume of sound delivered from the projectors.

Fig. 4 shows the circuit combination required when a connection is to be established to a distant city where the loud speaking receivers are located. In the city where the speaker is located, connection is made to the toll office by means of a non-loaded cable circuit equipped with an equalizer similar to Fig. 3. A volume indicator V_1 is associated with the amplifier C_1 at the toll office to enable proper adjustment of amplifier C_1 to be made so that the power delivered to the toll line will be within the proper limits. As explained above if the volume at the toll office is allowed to become too great, the telephone repeaters on the toll line will be over-loaded and serious distortion will result, while if the volume is allowed to become too weak, extraneous noise and crosstalk will tend to obliterate the direct transmission. If a distant talking transmitter is used for the speaker, a multi-stage adjustable amplifier is associated with it. In this case the volume indicator is located at the output of this amplifier as shown by the dotted lines in Fig. 4. When the volume indicator is employed at this point it is necessary to take into account the loss introduced by the non-loaded cable and the equalizer E_1 , together with the gain of the repeater C_1 , in order to deliver volume within proper limits to the toll line. The toll line, shown equipped with repeaters D_1, D_2 , etc., extends to the toll office in the distant city.

3. Clark. *loc. cit.*

At this point the amplifier C_2 is located, together with another equalizer E_2 , for correcting the distortion in the local non-loaded cable circuit. The apparatus at the point where the audience is located is similar to that shown in Fig. 3.

Fig. 5 shows the circuit combination employed when a local address is to be given, while at the same time the same address is delivered to one or more distant points. In order to allow the local audience to hear the address by means of the loud speakers, the power amplifier B

FIG. 5—ONE-WAY CONNECTION FOR ADDRESSING LOCAL AND DISTANT AUDIENCES SIMULTANEOUSLY

supplying energy to these is bridged across the output of the amplifier A associated with the transmitter T . A volume indicator V , connected across the circuit at the point where the bridge is made, makes it possible to maintain constant volume both for the local loud speakers and for the transmission applied to the toll lines by suitable adjustment of amplifier A . At the toll office means are indicated for connection to two distant points X and Y . Owing to the fact that amplifiers C_1 and C_2 are one-way devices, no interactions can occur between lines X and Y or between these lines and the local loud speaking system. The arrangements for reaching the distant points X and Y are similar to the one illustrated in Fig. 4.

All of the circuit arrangements which have so far been described are arranged simply so that a speaker may address one or more local or distant points. When it is

FIG. 6—TWO-WAY FOUR-WIRE CONNECTION FOR ADDRESSING LOCAL AND DISTANT AUDIENCES

desired that the speaker and the audience at the sending end be able to hear, also, a speaker at the distant point, more complicated arrangements are required.

Fig. 6 shows a circuit arranged for such two-way service, the line being operated on the four-wire principle, *i. e.*, two separate transmission paths are provided, one for transmission in each direction. The circuits connecting transmitter T_1 with the projector group R_2 and transmitter T_2 with the projector group R_1 are similar to the circuit in Fig. 4. By-pass connections F_1 and F_2 are added at the two ends which allow part

of the output of each transmitter to pass into the local loud speakers. These by-pass connections are so arranged that transmission can pass only in the proper direction. Two volume indicators are provided at each end. Referring to the left-hand terminal, volume indicator V_1 is provided to insure that power is supplied to the toll line within the proper limits of volume, as explained above. V_3 is provided to facilitate adjustment of the by-pass circuit F_1 and of amplifier B_1 so as to deliver proper volume from R_1 both for the local talking and for the reception of the addresses from the distant end of the circuit. The volume indicators V_2

FIG. 7—TWO-WAY TWO-WIRE CONNECTION FOR ADDRESSING LOCAL AND DISTANT AUDIENCES

and V_4 at the right-hand end of the circuit have functions similar to those of V_1 and V_3 respectively.

Fig. 7 is similar to Fig. 6 with the exception that the toll line is of the two-wire type. At each end of the toll line, which may, or may not, contain two-way repeaters, transformers and networks N_1 and N_2 are placed for converting the two-wire circuit into a four-wire circuit. The equalized cable circuits at the two ends thus form two sides of short four-wire circuits. The conditions of balance between the networks and the toll lines prevent more than a very small amount of

FIG. 8—ARRANGEMENT FOR CONNECTING THIRD POINT TO CIRCUIT OF FIG. 7

the direct transmission from each local transmitter from entering the local loud speaking receiver circuit at the points where the local circuits connect to the toll line. Practically all of the transmission from transmitter T_1 to projector group R_1 and from transmitter T_2 to projector group R_2 is delivered through the adjustable by-pass circuits F_1 and F_2 , respectively.

For connections requiring to and fro conversations between three or more points, all of which may be equipped with loud speakers, intermediate points may

be connected to a two-wire telephone circuit by employing the arrangement shown in Fig. 8. A three-winding transformer is inserted in the toll line which is so constructed that the impedance which it introduces into the circuit is small enough to avoid a serious irregularity. Talking currents are put out on to the toll line through this transformer. The received transmission is obtained from a high impedance bridge across the midpoints of two of the windings of the three-winding transformer. Amplifiers C_1 and C_2 introduce sufficient gain to overcome the losses due to the inefficient coupling with the telephone line. The rest of the circuit at the intermediate point is the same as Figs. 6 and 7, the local speaker being heard by his own audience by means of transmission delivered through by-pass F . A modification of the arrangement of Fig. 8 can, of course, be used with a four-wire toll circuit.

ARRANGEMENTS FOR ARMISTICE DAY, 1921

Fig. 9 shows the circuit which was employed on Armistice Day, 1921, when audiences of 100,000 people

amplifier A_2 , separated into two branches, one branch going to the local amplifier B_1 , which supplied the local loud speakers R_1 , the other going to the telephone circuit through amplifier C_2 , switch S_1 and amplifier C_1 . The switch S_1 was provided for connecting either the announcing transmitter T_1 or one of the transmitters for picking up the ceremonies to the end of the toll line. V_1 and V_2 are volume indicators, V_1 being employed to indicate that the proper power was being put into the toll line, while V_2 furnished an indication of the volume which was being delivered by the projector group R_1 . During the ceremonies the amplifier C_2 was continuously adjusted so as to deliver proper volume to the long distance telephone circuit, the volume indicator V_1 making it possible to keep the volume applied to the toll line within close limits. At the same time independent adjustments were made of the amplifier B_1 to take care of the varying conditions introduced by the different talking conditions as well as the varying conditions introduced by shifting of the crowds listening to the ceremonies.

FIG. 9—CIRCUIT USED FOR CEREMONIES ON ARMISTICE DAY, 1921

at Arlington, 35,000 people at New York and 20,000 people at San Francisco, joined in the services at the burial of the Unknown Soldier. This was the first time that audiences at more than one distant point were simultaneously addressed from one point by means of the public address system.

At Arlington three different transmitters T_2 , T_3 and T_4 were used for the different parts of the ceremonies. T_2 was used for the musical selections, T_3 for the speeches made in the amphitheatre, and T_4 for the speeches at the grave of the Unknown Soldier. Another transmitter T_1 was provided for the use of an announcer who kept the audiences at New York and San Francisco advised of the proceedings. The speech currents leaving these transmitters were brought up to moderate volume by means of amplifiers A_2 and A_1 , the former taking care in turn of the three different transmitters employed during the ceremonies.

The voice currents from the transmitters which were employed for the ceremonies, after passing through

After leaving the amplifier C_1 at Arlington, the voice currents first passed through a non-loaded section of cable whose distortion was corrected by equalizer E_1 . A non-loaded 8-gage open-wire circuit carried the voice currents to New York City. At this point, the circuit again branched, one branch delivering a part of the voice currents to the apparatus at Madison Square Garden, the other branch going to San Francisco over one of the non-loaded No. 8 gage transcontinental circuits. The arrangements employed at Madison Square Garden and at the Civic Auditorium in San Francisco were similar, switches being provided at each point to connect to the projector groups the circuit from Arlington or from the local transmitter.

The difficulties involved in transmitting voice currents for the first time to loud speaker installations at distant points, as well as the great importance of the occasion, made it necessary to take elaborate precautions in order to insure the success of the undertaking. The long distance telephone circuits were

the ceremonies at the grave, therefore, these loud speakers were disconnected and those numbered 22 to 26 used instead. Also in order to properly cover the inside of the amphitheatre during the ceremonies at the grave, the small projectors 30 and 33 were used. These were located on the arch over the platform and were directed at the front seats in the amphitheatre.

The projectors were divided up into a number of small groups and so connected that the volume of sound delivered by each group could be varied without affecting the other groups. This was necessary in arriving at the power to be delivered by each projector to give uniform distribution and to avoid interference between different groups.

By means of these arrangements all parts of the ceremonies were carried to all parts of the audience at the National Cemetery and were also delivered by means of the lines to the audiences in the distant cities.

At New York, a group of fifteen loud speakers was used in Madison Square Garden to satisfactorily reach all parts of the audience and a group of twenty-one loud speakers was suspended outside the building for the outside audience. At San Francisco, ten loud speakers were used in the Civic Auditorium and seven outside.

USE OF PUBLIC ADDRESS SYSTEM APPARATUS WITH RADIO

When radio broadcasting came into general use, the apparatus and methods which had been developed for the public address system were applied to this new field as it also demands high quality reproduction for speech and music. The transmitters and amplifiers associated with them in the public address system are used in radio broadcasting studios for delivering speech frequency electrical power to the radio transmitter. Loud speaking receivers and amplifiers for delivering sufficient power to operate them are used with many of the radio receiving sets.

The methods which have been employed to connect public address system transmitters with toll lines are being used for the broadcasting by radio of speeches and music given at points remote from the radio station. In such cases the transmitter and its associated amplifier are operated and controlled in the same way as described above for toll lines. In some cases the radio station is in the same city as the place where the speech or music is given and in other cases the two have been in different cities. In the first case the output of the transmitter amplifier is carried to the radio station over non-loaded cable circuits which are equalized by means of distortion correction networks to have uniform efficiency over a wide frequency range, in some cases up to 5000 cycles. Where the two points are in different cities, the non-loaded cable circuit goes to the toll office

and there is connected to the toll lines which are operated in the same manner as described above for loud speaker use.

For some of the higher grade music, such as that given by symphony orchestras, the less efficient, but slightly higher quality condenser type transmitter has been used instead of the double button carbon type. This requires the use of an additional two stage amplifier in front of the regular three stage transmitter amplifier.

The output of the transmitter amplifiers is controlled with the aid of a volume indicator bridged across the output terminals of the amplifier. For best results, particularly in reproducing music, it is necessary to adjust the gain of these amplifiers to compensate partially for the large range in the volume of the music. If the amplifiers are set high enough in gain to send through the low passages of the music with sufficient volume so that it will override the static and the interference from other sending stations, the loud parts of the music will seriously overload the radio transmitter system, unless it is of very large capacity, and will in general overload the receiving sets. Furthermore, putting out these loud parts at the same relative level with respect to the low passages as they are given by the orchestra, makes the interference between radio stations more serious. In some orchestral concerts the power amplification of the transmitter amplifier has been adjusted over a range of more than a hundred to one, these changes being made, however, so that they were not noticed by those listening to the concert by radio.

Proper volume control is very important in picking up such music for radio broadcasting. The lack of such control is responsible for many of the poor results that are being obtained. In this connection, the location of the transmitter with respect to the various instruments in the orchestra or smaller combination of instruments, so as to maintain in the reproduced music the proper balance between the several parts is, of course, of great importance.

An interesting illustration of the combination of the public address system, telephone lines and radio broadcasting was used in connection with reporting a football game played in Chicago in the fall of 1922. By means of high quality transmitters and amplifiers located at the football field, announcements of the plays and the applause of the spectators were delivered to a cable circuit extending to the toll office in Chicago. This circuit was connected there to a toll line to New York where it delivered the telephonic currents to a radio broadcasting transmitter. In Park Row, in New York City, was located a truck on which was mounted a radio receiving set arranged to operate a public address system. By this means the reports of the plays of the football game in Chicago were delivered to a large crowd in the streets of New York.

Discussion

DISCUSSION ON "PUBLIC ADDRESS SYSTEMS" (GREEN AND MAXFIELD) and "USE OF PUBLIC ADDRESS SYSTEM WITH TELEPHONE LINES"

(MARTIN AND CLARK)

New York, N. Y., February 14, 1923

Frank B. Jewett: To you, members of the American Institute of Electrical Engineers, and to you, our guests assembled together in New York and Chicago, I wish in opening this first evening meeting of our Midwinter Convention especially to call your attention to the unique significance of the occasion which brings us together and of the epoch in engineering history which it marks, not only in electrical development but in the conduct of human affairs as well.

For the first time in the history of the world, groups of men and women, separated by hundreds of miles, are gathered together in a common meeting under a single presiding officer to listen to papers presented in cities separated by half the span of a continent, and to take part in the discussion of these papers with an ease characteristic of discussions in small and intimate gatherings. At the same time unnumbered thousands in their homes are auditors of our deliberations through radio broadcasting.

Who can picture the limits of the effect and influence which will flow from the developments of electrical science and electrical engineering which have made this night possible. In truth, we are participants in an historical event and our children, nay even many of us, may see the agency we here use employed with mighty effect in controlling our collective relations in state and nation. Someone has said that the greatest political engine ever devised was the colonial town meeting where every question of importance was debated and discussed in an open forum of all the citizens. Be that as it may, we are well aware that our best government today is found in those small political units where the town meeting in some form is feasible and still persists. It is only when we come to the larger units of city, state and nation that the limitations on common discussion of vital matters, which are imposed by sheer physical size, evidence themselves in cumbersome and inadequate substitutes for personal discussion and oft-times in unsatisfactory results.

May it not be that in this two-way working telephone with its sensitive transmitters and loud speaking receivers we have the instrumentality for insuring a simpler and better ordering of our affairs—an instrumentality which will enable us to derive many of the benefits of the town meeting in the greater concerns of our national life. The mechanism which we are here using is one adapted to permit many speakers in many distant audiences to be heard by all who care to listen and take part in a common discussion. In voicing the opinion that this mechanism is destined profoundly to affect our political and economic machinery, I intend to convey no thought or picture of a pure democracy but only of a representative form of government in which all questions that would be helped by oral discussion can be so discussed without restraint from the physical limitations of the human voice or of distance. They might be discussions between widely separated groups on some matter of common concern or between a designated representative and his constituents, or in any of the thousand and one ways in which human beings better their conditions by oral discussion.

In the hands of the members of this Institute the telephone has been developed from the first crude concept of Alexander Graham Bell's great contribution to knowledge and great gift to mankind, into a machine of incalculable influence in human affairs. The successful realization of a dream, a hope and an inspiration dating back to the pioneer days of Bell himself, namely, the production of a loud speaking telephone which would reproduce the human voice faithfully but in stentorian tones and in many places simultaneously has now been accomplished. In the solemn exercises attendant upon the burial of the Unknown

Soldier at Arlington on Armistice Day a year ago, we had the curtains of the future drawn partially aside and saw vast audiences in New York and San Francisco co-mingled, as it were, with those who listened on the banks of the Potomac, but those exercises and all subsequent exercises and demonstrations have been in the nature of one-way transmission; that is, they have been arrangements in which the speakers were at one place and the audience at one or more other places, or they have been arrangements where a single audience listened to speakers in different places. Tonight, for the first time, we are witnessing and making use of the next step in the development by employing an arrangement which enables many speakers and many audiences in many places to meet as one body.

From the arrangement at Arlington to that of tonight may seem a logical next step. So it is for those who have the imagination to picture the future, but so too was the concept of a loud speaking telephone a simple logical next step to anyone who had witnessed the operation of an ordinary telephone. In both cases the next step that was easily logical in the imagination has been technically difficult in reality. It is neither my purpose nor my place as the presiding officer to trench upon the papers and discussion intended to describe and exemplify this new instrumentality. Before proceeding to the more formal part of our program, however, I wish merely to call your attention to the fact that we lack only direct distant vision to make this joint meeting one in very fact save only for the element of the personal proximity of those in attendance, and who among us is hardy enough to believe that this last limitation may not be removed within the lifetime of many of those now here. Fundamental and applied research are opening new doors daily in bewildering succession. When they open that last door which now prevents man from exercising at a distance all of his powers of personal intimate communication we will have another noteworthy meeting of this Institute.

Tonight, however, we must be content with full powers of speech and hearing but with partially defective vision. So it comes about that you, Mr. Schuchardt, our Vice President, in Chicago, and you, Mr. Rhodes, my Vice-chairman, are each in a unique position, a position in which one of you is acting in place of the President at a meeting where the President himself is in attendance in his official capacity, and the other is acting similarly for the President in his capacity as presiding officer. Some day this may not be necessary, but for the moment we are really acting as the eyes of this great joint meeting and are transferring as best we can the functions of distant vision by means of human speech.

R. F. Schuchardt: Mr. President, members and guests of the Institute gathered in the metropolis on the Atlantic shores and in this active city of the great central west, and those many others who with radio detectors are participating in this truly national meeting:

This is indeed a wonderful experience for all of us—an epoch-making event in history, as you, President Jewett, have so well said. Through the agency of devices which are already the familiar tools of telephone engineers, though still marvels to most of us, we are living for a few hours this evening in the identical mental atmosphere though vast stretches of our country separate us physically. In contemplating the means which make all this possible we recognize the debt that the world owes to the men whose achievements this represents—the patient, enthusiastic, talented engineers of the American Telephone & Telegraph Company and of that splendid Research Bureau of the Western Electric Company where Col. Frank B. Jewett has played such a leading role.

Never in history has there been such advance in the things that progress civilization, chief among which is transportation—transportation of material things, as done by the ocean greyhounds that bring Europe within a few days of our eastern coast and by the railroads that cross the continent in even less time,

and now also by the still swifter airships; transportation of energy from hydro or steam plants over great electric transmission lines to distant markets; and that transportation of thought, the broadcasting of intelligence, that we enjoy this evening. All of these things annihilate distance and bring people closer together, into more intimate kinship. Yet we have the paradoxical situation that in the past decade, in the midst of this advance, there occurred the greatest outburst of barbarism known to the history of civilization.

The Phoenix that rises from the ashes must be largely the work of the engineer, and what can be more potent here than this contribution of the telephone engineer. President Jewett has eloquently pictured its possibilities in relation to our national affairs and no doubt his picture will materialize. May we not hope that the ease with which peoples on opposite sides of boundary lines in Europe can thus be brought together, ear to ear, if not face to face, will serve powerfully to show them that their fundamental interests and their aspirations are common and in reality they are all kin. The engineers of those countries must and will lead the way.

This wonderful work of the American telephone engineer, so forcefully brought home to us all by this evening's experience, will serve as an inspiration to engineers in other fields. It emphasizes splendidly the great value of engineering research, it stimulates the imagination, and will encourage others to renewed efforts. The engineer appreciates his obligation for worthwhile accomplishment for the common weal, and he rejoices in all opportunities in which to express this appreciation.

In conclusion, Mr. President, may I tell you how deeply the Great Lakes District feels the honor and the special favor of being permitted to join in this memorable meeting so uniquely, and we thank you and your associates for making this opportunity possible.

E. B. Craft: The papers to which we have listened this evening establish another milestone in the art of electrical communication.

The system which has been described and demonstrated for us would seem to almost complete the picture of the possibilities of the transmission and reception of the spoken word.

During the past ten years we have seen the range of the wire communication systems extended so that it is now possible for an individual to converse directly with any other *individual* within the confines of the continent.

The developments in radio broadcasting during the same period have made it possible for an individual to speak directly and simultaneously to *unlimited numbers* of individuals located at a similar number of different points.

Now this latest development which we have christened the public address system, adds another and tremendously important possibility which is that an individual may converse directly with *groups* of individuals of practically unlimited size. Furthermore, they can be assembled in direct view of the speaker or through the agency of wires or radio these large groups may be located anywhere within the confines of our land, on the islands adjacent or on the ships at sea.

Truly we have in these agencies all that would seem essential to Man's dream of universal intercommunication.

It may be of interest to consider briefly some of the possible uses to which this new instrument may be put.

It is a noteworthy fact that many of our largest and most beautiful places of assembly are, in spite of their costliness and artistic perfection, sadly deficient in their acoustic qualities. Through the use of the system which we are now considering, the limitations which seem to be inherent in the design and construction of many of these great structures, are removed, their usefulness as places of public assembly fully attained.

In outdoor spaces Man's voice is a rather puny thing, but now science has brought to his aid a perfectly controlled volume of energy by which his voice may be made to reach audiences of

thousands of persons, many of whom would, under former circumstances, be merely indifferent onlookers.

The growth of our urban centers has reached such a point that for an individual to speak directly and at one time to any considerable portion of its inhabitants has become a physical impossibility. These physical limitations have been removed and the public speaker will now be able to much more effectively play his part in developing and molding public opinion.

In rural communities it is seldom, if ever, that any considerable number of its inhabitants have the opportunity to hear the voices of our National figures. On great public occasions whether they be State or National, it will now be possible for these people to gather in their local centers and have the voices of public men and the music of great bands or orchestras brought directly and naturally to their ears, whether the event itself be a hundred or a thousand miles away.

One could go on indefinitely and enumerate specific examples of the valuable applications of this new development, but it seems sufficient to point out some of these broader applications and to express the confidence that as new uses arise, the technical means will be available to accomplish the desired results.

B. E. Sunny: The American Institute of Electrical Engineers is tonight collecting an extra dividend on its investment, *in time and effort*, in helping for so many years in the development of the electrical industry.

It is holding a joint meeting in New York and Chicago by means of the long distance telephone and the loud speaker. The occasion is a scientific triumph, in the achievement of which, the Institute will cheerfully be given a generous share.

For forty years it has been the international agency for assembling and coordinating the human elements required by a new industry of unlimited significance in its possibilities for public service.

It has been the common gathering place.—the home, in fact, of the fraternity, where theories and problems have been fully and frankly discussed. It has been the clearing house for electrical ideas, plans and methods. In its meetings the rivalries growing out of keen and continuous competition have been forgotten, and a spirit of unity has always prevailed.

The success in the various branches,—electric lighting, transportation, telephone, etc., has necessarily come by slow degrees, but at a very much earlier date than could have been the case, were it not for the opportunities and assistance given by the Institute.

The awarding of the Edison Medal is one of the inspiring and stimulating processes of the Institute, by which 14,000 or more men are held together, in an earnest and enthusiastic campaign for the advancement of the profession.

The Edison Medal is an impressive tribute to the men who, in a large degree, represent the remarkable strides that have been made in modern electrical application.

In the list are men who differed in their theories and practises with respect to manufacture and operation, but these differences have long since been disposed of by the law of the survival of the fittest, which seems to have unusual applicability to electrical ideas.

The public service is no respecter of persons and, as the final judge, accepts or rejects our efforts, without emotion.

The contributions to the art by each of these men have been tremendously important and valuable, and they are highly deserving of the distinguished recognition they have received. In their genius, industry, integrity, leadership and achievements, they are our glory, and we are indebted to the Institute for having placed them in our Hall of Fame.

We members of the Institute who have felt that the many important discoveries and inventions in electricity should give us permanently a place in the center of the stage, in the strong light of public approval, are gratified at the announcement by our brothers in the medical profession that they have found the

Telephone Transmission Over Long Cable Circuits

BY ALVA B. CLARK

Member, A. I. E. E.
American Telephone & Telegraph Co.

Review of the Subject.—The application of telephone repeaters has made it possible to use small gage cable circuits to handle long distance telephone service over distances up to and exceeding 1000 miles. A general picture of the long toll cable system which is being projected for use in the northeastern section of the United States was presented recently by Mr. Pilliod before this Institute.*

Many of the circuits in these toll cables are so long electrically that a number of effects, which are comparatively unimportant in ordinary telephone circuits, become of large and sometimes controlling importance. For example, the time required for voice energy to traverse the circuits becomes very appreciable so that reflections of the energy may produce "echo" effects very similar to echoes of sound. The behavior of the circuits under transient impulses, even when two-way operation is not involved so that "echoes" are not experienced, is very important. In order to keep

*JOURNAL of the A. I. E. E. Vol. XLI, 1922, August, p. 585.

within proper limits of variation of efficiency with frequency over the telephone range special corrective measures are necessary. Owing to the small sizes of the conductors, the attenuations in the longer circuits are very large. Special methods are, therefore, required to maintain the necessary stability of the transmission, including automatic means for adjustment of the repeater gains to compensate for changes in the resistance of the conductors caused by temperature changes.

THIS paper aims to present an idea of what is involved in the transmission of voice currents over long toll cable circuits. Because of the breadth of the subject covered, no attempt has been made to make the discussions of the various items complete, or to include many of the results of the experimental and theoretical work which contributed to a solution of the problems and which has involved the cooperative efforts of a large number of engineers and investigators. This paper should be considered merely as an introduction to the subject. It is hoped that subsequent papers will

important effects encountered in long cable circuits are discussed and their reactions on the design of cable systems indicated.

In view of the discussion on telephone repeaters given in the Gherardi-Jewett paper,¹ which was presented before this Institute on October 1, 1919, it will be assumed that the reader of the present paper is familiar with the general features possessed by the various types of such devices and, accordingly, no descriptions of them are given, their over-all performance only being of interest in the present connection.

FIG. 1—DIFFERENT TYPES OF CABLE CIRCUITS

be presented dealing with these matters in more detail.

For the benefit of those who are not intimately in touch with telephone transmission work, the different types of circuits used in toll cables are first briefly reviewed. The important characteristics of the loading systems are then presented. Following this, various

DIFFERENT TYPES OF CIRCUITS

The different types of circuits used in toll cables are illustrated in diagrammatic form in Figure 1. Circuit "b" is a two-wire telephone circuit employing a 21-type telephone repeater. This type of circuit is employed

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 14-17, 1923.

1. TRANSACTIONS of A. I. E. E., Vol. XXXVIII, Part II, p. 1287.

for handling connections on which but one tele-repeater is involved. Circuit "c" is a typical re circuit on which the familiar 22-type telephone rs are operated. Circuit "d" is of the four-wire hich employs two transmission paths, one for rection. The function of the pilot wire circuits, ll be taken up later.

the exception of circuit "b", which possesses itation that it cannot advantageously be con-to another circuit containing telephonerepeaters, uits shown in the figure may be connected, when d, to circuits of the same or other types, such as ire circuits, to build up various telephone cons. In general, circuits such as "c," employing repeaters, are used for handling connections of te lengths, while circuits such as "d" of the four-e, are employed for the longer connections where rmission requirements are more severe.

ldition to employing the cable conductors for ng telephone service, these may also be arranged ish d-c. telegraph service. Apparatus for tting the circuits so as to permit this super-

of the d-c. telegraph is indicated on the draw- n general, the method of compositing the small ble circuits is the same as that employed for tting open-wire lines. The telegraph circuits, however, operate with a metallic instead of a d return and employ much weaker currents than ommon on open wires. Telegraph currents d in the cables are comparable in magnitude voice currents.

wo-wire circuits in toll cables employ conductors 9 or No. 16 A. W. G. while for the four-wire

No. 19 wire conductors are usually em- (No. 19 wire weighs $20\frac{1}{2}$ pounds per wire 5.8 kilograms per kilometer. No. 16 wire wice as much).

LOADING CHARACTERISTICS

weights of loading are usually employed. These nonly known as "medium heavy loading" and ght loading" and in this paper they will be to for brevity as "m. h. l." and "x. l. l." ely. The medium heavy loading employs ing an inductance of about 0.175 henry in the uits, spaced 6000 feet apart, (approximately eters); the extra light loading employs coils n inductance of about 0.044 henry for the side wth the same spacing. The capacity per ection for the side circuits is approximately rofarad.

edium heavy loaded side circuits have a istic impedance of about 1600 ohms, and a eQUENCY of about 2800 cycles. The extra led side circuits have an impedance of about ; and a cut-off frequency of about 5600 cycles.

shows the attenuation-frequency character- No. 19 and No. 16 side circuits with the two

types of loading. It will be observed that the m. h. l. circuits have lower attenuation for frequencies below about 2500 cycles, as should be expected from the fact that the inductance per mile introduced by the loading coils is greater. However, the attenuation is more nearly equal at different frequencies in the case of the x. l. l. circuits, this being particularly true at the higher voice frequencies.

Another important characteristic of loaded circuits when repeaters are involved is their velocity of propagation. Since the inductance per mile of x. l. l. circuits is only $\frac{1}{4}$ of that for m. h. l. circuits, the velocity of propagation is twice as great for the x. l. l. circuits as indicated by the well-known approximate formula

$$V = (LC)^{-\frac{1}{2}}$$

Where V is the velocity in unit lengths per second, L is the inductance in henries per unit length and C is the capacity in farads per unit length, the unit of length for expressing velocity, inductance and capacity being the same.

FIG. 2—ATTENUATION-FREQUENCY CHARACTERISTICS OF LOADED CABLE SIDE CIRCUITS

The x. l. l. type of loading is best for the longer circuits, because of the more nearly equal attenuation of currents of different frequencies, its higher velocity of propagation which permits more efficient operation of telephone repeaters, and also its comparative freedom from transient effects, as will be explained in more detail later. For the shorter circuits where these effects are not so important, the m. h. l. type is satisfactory electrically and is therefore employed, since fewer repeaters are required owing to the lower attenuation.

"ECHOES"

As is well known, whenever points of discontinuity or unbalance occur in a telephone circuit, reflections of electrical energy take place. If the circuit is long so that the time for transmission is appreciable and if also the losses are not so great as to cause the reflected energy to become inappreciably small before it reaches the ear of a listener, echo effects will be experienced. While, in general, reflections take place in any telephone circuit actual echoes are never appreciable unless tele-

phone repeaters are employed. In the case of circuits with repeaters, the electrical length is usually great enough so that an appreciable length of time is required for the voice currents to travel to some discontinuity and back again. Furthermore, the repeater gains keep the reflected voice currents large.

It should be understood that the echo effects which are experienced in long repeated circuits are due to the same unbalances, which, on shorter circuits, bring in trouble due to "singing," or distortion of the voice waves due to "near-singing." On electrically long circuits, due to the comparatively great time lags involved, the echo effects become of controlling importance. Consequently, it is, in general, necessary on such circuits to work the repeaters at gains well below those at which "singing" or distortion due to "near-singing" is experienced.

The echo effects which occur in four-wire circuits will first be discussed, since the effects are simpler in this case than they are in the case of a two-wire circuit.

Fig. 3a shows a four-wire circuit in diagrammatic form, while Fig. 3b shows the echoes which are caused by the unbalances at the terminals. When someone at terminal A talks to a person at terminal B, the heavy line in Fig. 3b shows the direct transmission, which takes place over the top pair of wires in Fig. 3a. When this current reaches the distant terminal, part of it goes to the listener while another part, due to the imperfections of balance between the line and network at that terminal, travels back through the pair of wires at the bottom of Fig. 3a toward terminal A. The talker at terminal A will hear this current as an echo if

FIG. 3—ECHO PATHS IN FOUR-WIRE CIRCUIT

the four-wire circuit is long enough so that the time lag is appreciable. This first echo heard by the talker divides at terminal A in the same way as did the direct transmission at terminal B, part of it taking the upper path of Fig. 3a back toward the listener. The listener will, therefore, first receive the direct transmission and then a little later an echo. This process is repeated producing successive echoes which are received at both terminals A and B as indicated.

A four-wire circuit 1000 miles (1600 kilometers) long has been set up in which the balances at the two ends

were deliberately made poor so as to exaggerate the effects. More than a dozen successive echoes could be heard before they became inaudible. Since for each echo the voice energy traveled 2000 miles (3200 kilometers) this energy must have travelled the distance around the world before becoming inaudible.

In order that a circuit will be satisfactory for regular telephone use, the echoes must be kept small as compared to the direct transmission. Evidently if the first echoes are small as compared to the direct transmission, the later echoes will be much smaller in magnitude. For example, if the power in the first echo,

FIG. 4—ECHO PATHS IN TWO-WIRE REPEATERED CIRCUIT

heard by the listener, is 1/10 as great as the directly transmitted power, the second echo will have only 1/100 as much power, the third echo 1/1000, etc.

The velocity of an x. l. l. circuit is approximately 20,000 miles (32,000 kilometers) per second, while the velocity with m. h. l. is only 10,000 miles (16,000 kilometers) per second. It is thus seen that the time required for voice energy to travel from one end to the other of an x. l. l. circuit 1000 miles (1600 kilometers) long is 0.05 second. An echo traveling from one end of the circuit to the other and back again would, therefore, arrive 0.1 second behind the impulse which started the echo. With m. h. l. circuits these times are of course doubled.

Fig. 4 illustrates the condition existing in a two-wire circuit. For simplicity, the first echoes only are shown, the later echoes being less important owing to their comparative weakness as explained above. In such a circuit reflections occur not only at the terminals, but at a number of intermediate points in the circuit, the condition of balance between the networks associated with the telephone repeaters and the corresponding lines being necessarily imperfect. This imperfection of balance is due in part to lack of perfect balance of the apparatus closely associated with the repeater, and in part to the small irregularities which exist in the make-up of any practical loaded line. A further cause is the reflection at the adjacent repeaters, due to the difference between the repeater impedance and the line impedance.

It will be noted that three sets of echoes are shown which affect the "talker." In addition to these which involve one or more repeaters, a comparatively small

amount of power is reflected back to the "talker" from the various irregularities between the "talker" station and the nearest repeater. These reflections have not been indicated since their effects are of negligible importance. Six sets of echoes affect the "listener." Both for the echoes affecting the "talker" and the "listener," the dotted lines indicate reflections from a number of different points where irregularities exist as explained above.

In circuits containing a larger number of repeaters the numbers of sets of echoes affecting the talker and listener are, of course, greater. The number of sets of first echoes affecting the talker is equal to the number of repeaters. The number affecting the listener is equal to

$$\frac{N(N+1)}{2}$$

where N is the number of repeaters.

It is, of course, obvious, that for either four-wire or two-wire circuits, if the circulating energies are large, they will have an adverse effect on the ability of two people to carry on a conversation over a telephone circuit. Not only will the transmission received by the listener be adversely affected, but the talker will be considerably distracted, particularly when the time of the transmission over the circuit is so long that he hears a distinct echo of his words.

Experiments have shown that the effects of the echoes both on the listener and talker become more serious as their time lag is increased. This means that as telephone circuits are made longer it is necessary either to improve balances or to design the telephone circuits so that the velocity of propagation will be

FIG. 5—EFFECT OF ECHOES ON TALKER AND LISTENER

higher. This necessity for making the velocity of propagation high on long circuits was one of the principal reasons which led to the selection of extra light loading for the longer circuits.

Fig. 5 shows very approximately how the effects of the echoes vary with the length of time by which they are delayed. One curve is given for the effect on the "talker," another for the effect on the "listener." Both curves indicate, for various time lags, the comparative magnitudes of echoes which are small enough to be

inappreciable when ordinary telephone conversations are carried on. The curve applying to the "listener" is referred to the direct power which he receives, while the curve for the "talker" is referred to the power which he puts into the circuit.

In Fig. 4 showing the condition existing in a two-wire circuit, the comparative magnitudes of the power in each echo are indicated, a typical condition of the lines being assumed. For the listener the echo power is expressed as a percentage of the directly transmitted

FIG. 6—ECHO PATHS IN TWO-WIRE REPEATERED CIRCUIT WITH OMITTED LOADING COIL

power which he receives. In the case of the talker, it is expressed as a percentage of the power which he puts into the circuit. In addition to the comparative amounts of power in each echo, "weighted" magnitudes are indicated. The "weighted" figures take account of the fact that the effects of a given amount of echo become more serious as the time lag is increased as indicated by the curves in Fig. 5. Referring to Fig. 4, it will be noted that the "weighted" magnitudes of the power in the echoes are largest for the long paths. In general, this condition exists in the case of the majority of long two-wire repeatered circuits in cable.

In order to compare the behavior of a four-wire circuit with a two-wire circuit, consider again Figs. 3 and 4. It will be observed that in Fig. 4, showing the two-wire circuit, there is one echo received by the talker which travels from one end of the circuit to the other. Referring to Fig. 3 showing a four-wire circuit, it will be seen that this echo corresponds to the one labelled "1st echo, talker." Similarly for the echoes affecting the listener, the echo whose path is longest in the two-wire circuit corresponds to a similar echo in the four-wire circuit. Since many additional echo paths are present in the two-wire circuit, it is evident that, other things being equal, the over-all transmission result obtainable from the two-wire circuit cannot be made as good as that obtainable from the four-wire circuit.

In a two-wire circuit it is, of course, obvious that any defect in the lines which will cause a large irregularity will result in a considerable impairment of the circuit. Fig. 6 shows the effect of omitting a loading coil at an intermediate point in a circuit, the conditions in this circuit being assumed to be the same as those in Fig. 4

with the exception of the omitted loading coil. The omitted loading coil introduces a large impedance irregularity which causes certain of the echoes to be made much greater in comparative magnitude as indicated. In order to reduce the echoes in the circuit with the omitted loading coil sufficiently to make the circuit satisfactory for telephone use, it is necessary to reduce the repeater gains. In this particular case it is necessary to lower the total gain about four miles, which increases the over-all transmission equivalent of the circuit from about 10 miles for the normal condition to about 14 miles for the condition with the omitted loading coil.

Before leaving the subject of "echoes" it is believed that it will be of interest to point out some of the important characteristics of two-way repeatered circuits which result from these effects.

1. The minimum permissible net equivalent (total loss minus total repeater gain in one direction) of a four-wire circuit of a given length depends only on the velocity of propagation and the balance conditions at the terminals of the circuit. When conditions are such that the balance conditions cannot be improved, increasing the velocity of propagation will enable a lower net equivalent to be obtained.

2. In the case of a two-wire circuit with reasonably smooth lines, the exact location of the repeaters and the gains at which individual repeaters are worked have little effect on the over-all result so far as echo effects are concerned. This follows from the fact that the echo paths from end to end of such a circuit are usually of more importance than the shorter echo paths. Evidently, moving the individual repeaters about or altering their gains has no effect on the longest paths, provided the total gain in each direction is kept constant.

3. In the case of a two-wire circuit of a given length, the velocity of propagation and smoothness of the lines are of most importance in limiting the possible net equivalent, the line attenuation being of secondary importance.

For example, in the case of the transcontinental (New York-San Francisco) open-wire line, the original circuit was loaded. (Although this paper deals particularly with repeaters on cable circuits this example was selected because it illustrates this point so well). The velocity of propagation was such that voice currents required about 0.07 second to travel from one end of the circuit to the other. The total line equivalent was equal to about 56 miles of standard cable. By applying repeaters to this circuit it was possible to obtain a working net equivalent of about 21 miles.

The unloading of the circuit increased the velocity so that the time of transmission was reduced to 0.02 second, about 0.3 of the time required when the circuit was loaded. The attenuation was increased so that the total line equivalent without repeaters was equal to about 120 miles of standard cable, a little more than twice the equivalent of the loaded circuit. By applying repeaters of an improved type to this circuit so as to keep the quality good in spite of the increased attenuation and correspondingly increased gain required, it was possible to obtain a working equivalent of only 12 miles of standard cable as compared to the original figure of 21 miles. This means that with the same amount of speech power applied at one end, the power received over the non-loaded circuit is seven times as large as that formerly received over the loaded circuit.²

The example of the transcontinental line, above, may

2. A material improvement in the telephone quality was also effected by the unloading of the circuit.

well bring up the question as to why it is that cable circuits are loaded. This is done for two reasons: In the first place, it is in general cheaper to load cables than it is to make up the increased attenuation by means of more repeaters. In the second place the loading lessens the amount of distortion introduced by the cable circuits. In the case of open wire circuits, their series inductance is sufficient to keep the distortion small.

ATTENUATIONS AND CORRESPONDING AMPLIFICATIONS— POWER LEVELS

Owing to the fact that the weight of loading applied to the longest cable circuits is very light, the attenuation of such circuits is very great. A four-wire x. l. l. 19 gage circuit 1000 miles long has the enormous line equivalent of 500 miles of standard cable. The total power amplification applied to this circuit by the repeaters exceeds 10^{47} . This amount of amplification is more than enough to talk half way around the world at the equator using non-loaded No. 8 Birmingham wire gage open wire commonly employed for handling very long distance business (No. 8 B. w. g. copper weighs 435 pounds per wire mile, or 120 kilograms per kilometer).

In order to obtain an idea of how enormous this amplification is, assume that no repeaters were employed and an attempt were made to apply enough power at one end of the circuit to enable the normal amount of speech power to be received at the distant end. The power applied at the sending end would then have to be about 50 quadrillion times as great as the total power which it is estimated is radiated by the sun.

While the total amount of power amplification is very great, the amount of amplification put in at any one point is, of course, limited. The maximum amount of power at a repeater point is limited partly by the capacity of the vacuum tubes and partly by the power carrying capacity of the telephone circuit, including the loading coils. (By power carrying capacity is here meant the ability to carry voice waves without serious distortion.) It is also necessary to limit this power to avoid serious crosstalk into other circuits.

In addition to these limitations on the maximum power, it is necessary to insure that the power at any point in a circuit does not become too small. Otherwise the normal voice power will not be sufficiently large as compared to the power of crosstalk from other circuits. It is, furthermore, evident that the ratio of power from extraneous sources, such as paralleling telegraph circuits and power supply circuits, to the voice power should be as small as practicable in order to keep the circuits free from noise.

Fig. 7 will give an idea of how the telephone power attenuates and is amplified in a long circuit. The circuit shown is similar to those which it is proposed to employ between New York and Chicago, *i. e.*, it is a four-wire x. l. l. No. 19 wire circuit largely in aerial cable equipped with automatic means for compensating for

the changes in attenuation caused by the effects of varying temperatures on the resistance of the conductors. (These automatic devices are described in a later section of this paper.) For simplicity, the power levels for transmission in one direction only are shown. The solid lines show the power levels when the temperature is a maximum so that the attenuations are greatest while the dotted lines show the levels when the temperature is a minimum and the losses are, therefore,

FIG. 7—POWER LEVELS IN NEW YORK-CHICAGO EXTRA LIGHT LOADED FOUR-WIRE CIRCUIT

also a minimum. The shaded areas between the lines represent the changes which take place during the course of a year.

When the requirement is introduced that transmission must take place in both directions it is found that at the points in the circuits going in one direction where the power is a maximum, the power going in the opposite direction in other circuits is a minimum.

effected by grouping the conductors in two bunches, one for transmission in one direction, the other for transmission in the opposite direction, taking care that these two bunches of conductors are separated electrically as far as possible. In the loading coil pots the coils employed on the circuits for transmission in the two directions are similarly kept separated. In the offices the separation is effected by arranging the repeaters and other apparatus as shown in the figure. It will be observed that no special separation is shown between the repeaters transmitting in the two directions, since to keep the conductors carrying weak power separated from those carrying strong power, it is merely necessary to keep the apparatus and cabling connected to the inputs of the repeaters separated from the apparatus and the cabling connected to the repeater outputs.

STEADY STATE DISTORTION

The possible sources of distortion may be divided broadly into (1) repeaters and auxiliary apparatus and (2) the lines.

With reference to the distortion introduced by the repeaters, the vacuum tube is fortunately very nearly perfect, at least in so far as concerns practical telephony. At one time, for purposes of test, a circuit was set up containing 32 vacuum tubes in tandem. On this circuit the distortion was so small that when listening to ordinary conversation it was difficult to detect any difference in the quality of transmission before and after traversing the 32 vacuum tubes.

FIG. 8—FOUR-WIRE SYSTEM—SEGREGATION METHOD TO REDUCE CROSS-TALK

This represents a very bad condition for crosstalk from one four-wire circuit into another. In order to overcome this the conductors carrying strong voice power are kept electrically separated or shielded from those carrying weak power as indicated schematically in Fig. 8. The conductors which carry strong voice power are shown heavy, while those carrying weak power are shown light. In the cable proper the separation is

It is beyond the limits of this paper to enter into the problems of design which were encountered in the development of the repeater circuits. For the present purpose of considering the over-all performance of repeated circuits in cable no serious error will be made if it is assumed that the complete repeater circuits meet the requirements for an ideal repeater as set up in the Gherardi-Jewett paper.

Considering next the lines, it is necessary to make the loading very regular so that balance difficulties will not cause an undue amount of trouble on two-wire circuits. Regularity of the loading is also essential in order to avoid irregular transmission of different frequencies. In order to secure this regularity of loading, it is necessary that the spacing between load-

FIG. 9—TRANSMISSION-FREQUENCY CHARACTERISTIC OF LONG EXTRA LIGHT LOADED FOUR-WIRE CIRCUIT

ing points be made very uniform and that the cable be manufactured so that the electrostatic capacity of its circuits be held within close limits. The loading coils themselves must be closely alike in their electrical properties and furthermore, the coils must be stable, *i. e.* these electrical properties must not change appreciably due to the passage of voice currents or other currents required for cable operation through them.

or net transmission equivalent plotted against frequency for an x. l. l. four-wire circuit 1080 miles long (1750 kilometers) which was set up for purposes of test. The heavy line in this figure shows the over-all result which was actually obtained with repeaters and associated apparatus designed to equalize the transmission, while the dotted line shows what the characteristic would have been had the repeaters introduced exactly the same amount of gain at all frequencies.

TRANSIENTS

In comparatively short telephone circuits, good quality will usually be assured if the transmission, as measured at different single frequencies within the voice range, is kept approximately constant. For electrically long circuits, however, this is not sufficient. Not only must the "echo" effects be kept within proper limits, but consideration must be given to the fact that when electrical impulses are applied to such circuits, peculiar transient phenomena are experienced. These transient phenomena occur in equal degree in two-way circuits and in circuits arranged to transmit in one direction only, that is, they are not related to "echo" effects.

In order to give an idea of the nature of some of the transient effects, some oscillograms are shown in Figs. 10, 11, 12 and 13. Fig. 10 shows an 1800-cycle current before and after traversing a cable circuit of an earlier type 1050 miles (1700 kilometers) long. This particular circuit was No. 13 A. w. g. weighing 82 pounds per wire mile (23 kilograms per kilometer) loaded with inductance coils of 0.2 henry spaced 1.4 miles (2.25 kilometers) apart and contained 6 one-way repeaters. It will be noted that the first sign of the arrival of the received

FIG. 10—TRANSIENTS IN NO. 13 MEDIUM HEAVY LOADED CABLE

Next, it is necessary to design the repeaters and associated apparatus used on the longer circuits, particularly the four-wire circuits, so as to put in different amounts of gain at different frequencies, thereby making the over-all transmission at different frequencies approximately constant in spite of the fact that the loss introduced by the cable circuits at different frequencies is not constant. Fig. 9 shows the over-all

current occurs about 0.1 second after the wave is put on at the sending end. This time checks with the formula for velocity given above. The time required after arrival of the first impulse (point "a") until the wave builds up to a practically steady-state condition at point "b" is about 0.055 second. The steady condition is interrupted at point "c" by the arrival of the break transient, the time interval between points "b"

FIG. 11—TRANSIENTS IN NO. 13 MEDIUM HEAVY LOADED CABLE

FIG. 12—TRANSIENTS IN NO. 13 MEDIUM HEAVY LOADED CABLE

FIG. 13—TRANSIENTS IN NO. 19 EXTRA LIGHT LOADED CABLE

and "c," representing the period when the wave is in the steady-state, being only 0.01 second. The wave required about 0.055 second to die out—interval between points "c" and "d."

It is interesting to note the behavior of the current during the building-up and dying-out intervals. During the building-up process the frequency of the received current increases from a very low value at point "a" until at point "b" it becomes the same as that of the source. The magnitude of the received current also increases until at point "b" it reaches a value corresponding to the steady-state transmission equivalent of the line. The interval "a-b" is determined solely by the structure of the line and has nothing to do with the time during which the current is supplied at the sending end.

The dying-out process can be considered to be caused by the application at the time of break of a second current equal in value to the current originally applied but opposite in phase, so that the sum of the two currents will be zero. Hence, it is to be expected that the received current will disappear by adding to the steady-state a transient similar to the building up transient in the interval "a-b." That this is true is indicated by the behavior during the interval "c-d." At first the low-frequency current of the break transient produces a displacement of the axis of the steady current. As the frequency approaches a steady value a beating effect becomes noticeable which grows smaller until complete opposition of phase obtains and the received current disappears.

Fig. 10 clearly indicates that a pulse of voice current having a frequency in the neighborhood of 1800 cycles, even though received in proper volume if steadily applied, would be badly distorted.

When carrying on a conversation over such a circuit as this, distortion of the voice waves makes understanding difficult while peculiar metallic ringing sounds are very noticeable.

Next consider a circuit of the same character with half the length. The effect of a circuit of this length on an 1800-cycle wave is shown in the oscillogram of Fig. 11. It will be observed that the propagation time has been cut in half while the lengths of time for the received wave to build up and die out have also each been cut in two. This checks with theoretical work, indicating that the severity of this type of transient effect is directly proportional to the length of the circuit. This fact that the transient effect is proportional to the length of the circuit furnishes the reason why a short circuit may give tolerably good results, while a long circuit gives poor results.

Fig. 12 is of interest as indicating what takes place when we apply a current at the sending end of the circuit whose frequency is so high that no appreciable amount of the steady current will pass through the circuit. In this case only transient oscillations appear at the receiving end of the circuit. This particular

circuit was of the same type as the above, although it was only 350 miles long (570 kilometers).

A large number of oscillograms of this sort have been taken in connection with the study of these transient effects. From these and theoretical considerations³ it has been proved that the effects in a given circuit are much worse at high frequencies than at low frequencies, the severity of the effects, within certain limits, being a function of the ratio of the frequency being transmitted to the frequency of cut-off of the loaded circuit. The gage of the circuit has practically no effect.

Since in order to give good quality it is necessary to transmit fairly well all frequencies up to at least 2000 cycles, it is obvious that on long circuits in order to keep the transient effects small, the frequency of cut-off must be kept high. In order to do this, it is necessary either to make the loading coils of very low inductance or to space them very close together. This is another one of the reasons why extra light loading was adopted for the long cable circuits. (It will be remembered that the inductance of the side circuit loading coils is only 0.044 henry and the spacing 6000 feet).

The effect of lighter loading on the transient behavior of telephone currents, is shown in Fig. 13, which shows a 2000-cycle wave transmitted over an x. l. l. circuit about 1050 miles (1700 kilometers) long. This circuit contained 23 one-way repeaters. It will be observed that both the building-up and dying-out transient periods are very much reduced, which means that all pulses of telephone currents up to at least 2000 cycles will pass through such a circuit with very little distortion.

STABILITY

As has been pointed out, the magnitude of the line transmission loss in a repeated circuit is of comparatively small importance in determining its possible transmission equivalent, whether the circuit be worked on a four-wire or two-wire basis. However, it is of extreme importance to be sure that the repeater gains are kept adjusted so as to compensate exactly for a large part of the transmission loss in the circuit, so that the difference between the total loss in the circuit and the total gain, which represents the net equivalent of the circuit, will be kept constant.

On certain of the long circuits this difference is very small as compared to the quantities which are subtracted. For example, in the case of a 1000-mile four-wire circuit using x. l. l. 19 gage conductors, the total line transmission loss is about 500 miles. Not counting the gain required to make up for losses in apparatus and office cabling, the total gain is about 488 miles, the difference, 12 miles, representing the net equivalent.

3. John R. Carson—"Theory of the Transient Oscillations of Electrical Networks and Transmission Systems." TRANSACTIONS of A. I. E. E. Vol. XXXVIII, page 407.

Evidently only a very small percentage change in either the transmission losses or the gains will have a large effect on the net equivalent. This represents about the most severe condition. Some examples of less severe conditions are:

2-Wire No. 19 m. h. l. circuit 200 miles long (320 kilometers). Line equivalent 58 miles. Repeater gain exclusive of gain required to make up for loss in apparatus and office cabling 46 miles. Net equivalent 12 miles.

4-Wire No. 19 m. h. l. circuit 500 miles long (800 kilometers). Line equivalent 145 miles. Repeater gain exclusive of gain required to make up for loss in apparatus and office cabling 133 miles. Net equivalent 12 miles.

In order to maintain the necessary constancy of the over-all or net transmission equivalent of long repeatered circuits in cable, it is necessary first of all to maintain the gains of the individual repeaters within close limits. In addition, periodic transmission measurements are required over the complete circuits, supplemented by suitable adjustment of certain of the individual repeaters whenever the over-all equivalent falls outside of the prescribed limits. Also, on the very

for one of the types of tube in common use are given in the following table:

Variable Quantity	Prescribed Limits	Gain Variation
Plate Potential.....	130 $\pm$ 5 volts	$\pm$ 0.2 mile
Grid Potential.....	9 $\pm$ 1 volt	$\pm$ 0.3 mile
Filament Current.....	1.25 $\pm$ 0.05 ampere	very small for new tube—one mile for tube just before replacement.

In addition to maintaining the tube currents and voltages within the required limits, the gains of the individual repeaters are checked periodically. Suitable adjustments are made when the repeater gains fall outside of the prescribed limits. When the filament emission of a tube becomes so low that the above specified variation in the filament current results in more than one mile gain variation, the tube is replaced.

A gain measuring device as indicated schematically in Fig. 14 is employed for this purpose. The measurement of gain is effected by comparison of the voltages across two resistances, one of which forms part of a

FIG. 14—DEVICE FOR MEASURING TELEPHONE REPEATER GAINS

long small gage circuits, the changes in attenuation, due to the resistance changes caused by temperature variations, become so large that it is practically essential to provide automatic means for overcoming these effects.

The methods employed in maintaining the gains of the individual repeaters and of the over-all transmission equivalents within proper limits will first be described, after which the automatic transmission regulators will be discussed.

IMPORTANT TESTS AND ADJUSTMENTS

In order to hold the repeater gains constant, close inspection limits are placed on the vacuum tubes during the course of manufacture to insure great uniformity of the product, as well as consistency of performance. In operating the repeaters, considerable care is taken to maintain constancy of the operating currents and voltages. The operating limits of currents and potentials together with the corresponding gain variations

circuit which includes the repeater, the other being simply a reference circuit. An amplifier-detector combination amplifies the voltages across these resistances and then rectifies them so as to obtain an indication on a d-c. galvanometer. Equality of voltages across the two resistances, which are designated as R and R' in the figure, is thus indicated by equal deflections of the galvanometer. When this condition is secured, the repeater gain is read directly from the dials A and B . By means of this device, it is readily possible to measure the gain of a repeater within a few tenths of a mile. Owing to the fact that the measuring circuits are comprised entirely of resistances, the readings of the set are independent of frequency, so that gains can be measured at all important telephone frequencies.

As pointed out above, transmission measurements over the complete circuits including the telephone repeaters are required at periodic intervals in order to insure that proper transmission standards are being maintained. By means of such measurements, the

variations in the over-all equivalent of the circuits due to the cumulative effect of small gain variations, slight variations which remain after the automatic transmission regulators have compensated for the major variations in the conductors and variations from other causes including the effect of different conditions of humidity on the wiring in the offices, are determined and compensated for. These measurements are made by applying a known electromotive force through a known resistance to one end of the circuit and receiving the current at the distant end with a suitable calibrated arrangement employing an indicating meter. Since this type of measurement is similar in principle to the method employed for measuring the gains of the individual repeaters, it will not be described.

means automatic. In the case of x. l. l. No. 19 circuits whose variation is greatest, it is necessary to locate the automatic regulators, in general, at every third or fourth repeater station in order to keep the transmission levels within proper limits. In Fig. 1a, a typical method of locating the regulating devices along a cable is indicated. In this sketch each square indicates a master automatic transmission controlling device while the loops extending in either direction from the squares indicate the cable circuits which control the functioning of these devices.

An automatic transmission regulator is shown schematically in Fig. 15. The device comprises a Wheatstone bridge arrangement. In one arm of the bridge, pilot wire pairs, extending in either direction in

FIG. 15—PILOT WIRE AUTOMATIC TRANSMISSION REGULATOR

AUTOMATIC TRANSMISSION REGULATORS

Since the resistance of long cable circuits employing small gage conductors is comparatively large, it is, of course, evident that changes in this resistance caused by temperature changes to which the cable circuits are subject will have a large effect on transmission. For example, in the case of an x. l. l. No. 19, 1000 mile circuit (1600 kilometers) in aerial cable, the total attenuation changes more than 110 transmission miles during the course of a year. This corresponds to a variation in the received power of more than 10^{10} or ten billion times.

It is, of course, essential to provide special means to counteract these effects. Furthermore, since the temperature changes which occur in an aerial cable are very rapid, it is practically essential to make these

the cable, are included as indicated in the figure. The Wheatstone bridge has associated with it certain apparatus which will not be described here in detail, which functions in such a manner as to keep the bridge automatically balanced at all times. In the process of maintaining balance of the bridge, angular motion is conveyed to a shaft which is proportional to the resistance variations which the cable circuits undergo. The movement of the shaft causes different contacts to be made and thus controls relays which in turn control the gains of the telephone repeaters, one way of doing this being indicated in the figure. The repeater gains are thus caused to be raised and lowered automatically, and thereby overcome the differences in attenuation caused by the temperature changes in the cable conductors.

Theory of Electric Wave Filters Built up of Coupled Circuit Elements

BY LEO J. PETERS*

Engineering Experiment Station, University of Wisconsin

Review of the Subject.—This paper is essentially a treatment of certain types of coupled circuit networks by methods similar to those used in the discussion of the properties of long lines with distributed constants. This method of treating those coupled circuit chains to which it can be applied far surpasses other methods of treatment in several important ways. First, the number of elements in the chain can be made as large as desired without complicating the problem in any way whatsoever. Second, the very method of treatment leads directly to the rational design of selective systems of a type which the older methods of treatment did not even show to exist. Third, this method of attacking the problem is much better adapted to a transient state treatment (following the methods of J. R. Carson and T. C. Fry) than the older methods of handling the coupled circuit problem.

In the second section of this paper there is developed the general theory of the properties of identical circuits coupled so as to form a chain. The equations giving the current and voltage of any circuit in the chain are identical in form with those giving the current and voltage at any point of a long line with distributed constants. The propagation constant however, instead of being an algebraic function of the circuit constants and the impressed frequency as in the case

for the line with distributed constants, is a transcendental function of the circuit constants and the frequency of the current being transmitted. The nature of this transcendental function is such that sharp changes occur in the characteristic curve which portrays the attenuation constant as a function of the frequency.

The third section shows how, by proper termination and design, these sharp changes in the attenuation frequency characteristic can be employed to build up filter networks.

The fourth section gives an application of the general theory by presenting a detailed treatment of simple series circuits magnetically coupled so as to form a chain. In this section a number of curves is presented. These curves give a visual picture of the general theory and bring out points useful in the designing of selective networks which must meet preassigned requirements.

The fifth section discusses the problem of building up filters using sections of many different types. General methods of attacking this problem are given and design formulas for three different types of filter sections which may be used together in building up a filter system, are derived. Curves are given which illustrate the methods of building up desirable characteristics. The design of selective systems is put upon a rational basis.

I. INTRODUCTION AND PURPOSE

The increase in the use of radio communication and the introduction of carrier current telephony has led to a very great interest in the problem of separating currents having frequencies which lie in a given band from currents of all other frequencies. Systems of circuits used to perform this separation have been called electric wave filters, or simply wave filters. Some of the properties of coupled circuits which make them valuable as wave filters have been known and employed for some time. It is the purpose of this paper to point out some new properties of certain types of systems built up of coupled circuits, and to show how systems having preassigned characteristics may be

built up in a rational way by an application of the theory presented.

In this paper chains built up of coupled circuits will be treated in a manner similar to that employed in arriving at the properties of long lines with distributed constants. In the telephone art it is common practise to give the transmission properties of long lines, or of any piece of apparatus by stating the loss in miles of standard cable or more rationally in attenuation units, incurred by inserting the line or the piece of apparatus between two points of known impedances. This method is very well adapted to a discussion of the properties of wave filters, and will be employed in this paper.

Wave filters built up of series and shunt impedances have been discussed by G. A. Campbell¹ and K. W. Wagner.² The general theory presented in the following sections is somewhat broader than that presented by Campbell and Wagner, as it includes as a special case the filter built up of series and shunt elements as the shunt element may be considered as a coupling element.

In this paper illustrations of the general theory will be given by discussing particular types of filters which are not built up of series and shunt elements. Illustrations from this class of filters are used because it is the application of long line theory to such coupled circuit chains which forms the main contribution of

*During the summer of 1921 the writer was employed as an assistant in filter design by the Western Electric Company. During this period he became very familiar with the series shunt type of filter element and with the methods used by the engineers of this company in handling filter design problems. This experience with the Western Electric Co. is reflected in this paper in such things as the loss method of treatment, the use of sections of different types to build up given characteristics, and the methods of obtaining the design formulas. The material for this paper was inspired by the previous work on coupled chains and on selective systems in general carried out by Professors Bennett, Crothers and the author at the University of Wisconsin. The general use of different equations in handling artificial line problems was acquired by the author from the published papers of Campbell and Carson. The conception of circuital and transfer impedance as a broad basis for filter theory and the type of filter section to which the treatment leads directly are thought to be original.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 14-17, 1923.

this paper to the literature on wave filters. The series shunt type of structure has already been described by Campbell and Wagner, and has been used for some time in the plant of the Bell Telephone System.

II. CURRENT PROPAGATION THROUGH A CHAIN BUILT UP OF IDENTICAL CIRCUITS COUPLED TOGETHER

(1) *General Equations and the Propagation Constant.* Consider the chain of circuits shown in Fig. 1. Each circuit is identical with every other circuit. The impedance of each circuit when removed from the chain and isolated is represented by Z_c . That is with the circuit taken out of the group and E volts impressed in it the current flowing would be E/Z_c . Z_c will be called the circuitual impedance. In general it will be of the form $a + jb$. The coupling is represented by the square box. The transfer or mutual impedance is represented by Z_m . That is the voltage in the $(q+1)$ th circuit due to the current in the q th circuit is $I_q Z_m$. In general Z_m may also be of the form $a + jb$. The source of power, represented by a generator works through an impedance Z_0 into a terminating circuit of half the normal circuitual impedance. The chain ends at the other end in a half circuit closed by a load impedance Z_n .

FIG. 1

Now applying Kirchoff's law to the q th circuit we obtain:

$$-Z_m I_{q-1} - Z_m I_{q+1} - Z_c I_q = 0 \quad (1)$$

The voltage across the mid-point of the q th circuit is:

$$E_q = -Z_m I_{q-1} - Z_c/2 I_q \quad (2)$$

Equation (1) is a difference equation relating the currents in three adjacent circuits. Its solution is:

$$I_q = A e^{q\tau} + B e^{-q\tau} \quad (3)$$

Substituting (3) in (1) there results:

$$\begin{aligned} Z_c/Z_m (A e^{q\tau} + B e^{-q\tau}) + A e^{-\tau} e^{q\tau} + B e^{\tau} e^{-q\tau} \\ + A e^{\tau} e^{q\tau} + B e^{-\tau} e^{-q\tau} = 0 \end{aligned} \quad (4)$$

Collecting terms:

$$\begin{aligned} Z_c/Z_m (A e^{q\tau} + B e^{-q\tau}) + A e^{q\tau} (e^{\tau} + e^{-\tau}) \\ + B e^{-q\tau} (e^{\tau} + e^{-\tau}) = 0 \end{aligned} \quad (5)$$

Factoring:

$$(A e^{q\tau} + B e^{-q\tau}) (Z_c/Z_m + e^{\tau} + e^{-\tau}) = 0 \quad (6)$$

If the first term were identically zero, no current would exist anywhere in the chain. The first term is therefore different from zero and we have:

$$Z_c/Z_m + (e^{\tau} + e^{-\tau}) = 0 \quad (7)$$

or

$$\cosh \tau = -\frac{Z_c}{2 Z_m} \quad (8)$$

In the long line theory τ has been called the propagation constant. This name will be retained here. Equation (8) is the fundamental equation relating the propagation constant to the circuit constants.

The constants A and B of equation (3) are arbitrary and may be determined in the terms of any two currents, any two voltages, or in terms of a current and a voltage at some mid-circuit position.

(3) *The Voltage Equation.* Upon substituting for I_{q-1} and I_q in equation (2) we obtain:

$$\begin{aligned} E_q = -Z_m (A e^{(q+1)\tau} + B e^{-(q+1)\tau}) - Z_c/2 (A e^{q\tau} \\ + B e^{-q\tau}) \end{aligned} \quad (9)$$

From equation (5) we obtain the relation,

$$\begin{aligned} Z_c/2 (A e^{q\tau} + B e^{-q\tau}) = -Z_m/2 (e^{\tau} + e^{-\tau}) (A e^{q\tau} \\ + B e^{-q\tau}) \end{aligned} \quad (10)$$

Substituting (10) in (9) there results

$$E_q = (-Z_m \sinh \tau) [A e^{q\tau} - B e^{-q\tau}] \quad (11)$$

From (8)

$$\begin{aligned} \cosh \tau = -\frac{Z_c}{2 Z_m}; \quad \sinh \tau = \sqrt{\frac{Z_c^2}{4 Z_m^2} - 1} \\ E_q = -\sqrt{Z_c^2/4 - Z_m^2} [A e^{q\tau} - B e^{-q\tau}] \end{aligned} \quad (12)$$

The term $\sqrt{Z_c^2/4 - Z_m^2}$ plays the same role here as the characteristic impedance, plays in long line theory. Therefore, this quantity will be called the characteristic impedance. It will be represented by the symbol Z_s . That is:

$$Z_s = \sqrt{Z_c^2/4 - Z_m^2} \quad (13)$$

$$E_q = -Z_s [A e^{q\tau} - B e^{-q\tau}] \quad (14)$$

(4) *Determination of the Constants A and B . In Terms of the Current and Voltage of the First Circuit.* When $q = 0$ let $E_q = E_0$ and $I_q = I_0$.

Then from (14) we obtain:

$$E_0 = -Z_s (A - B) \quad (15)$$

$$I_0 = A + B \quad (16)$$

$$A = 1/2 (I_0 - E_0/Z_s) \quad (17)$$

$$B = 1/2 (I_0 + E_0/Z_s) \quad (18)$$

The current and voltage equation then become

$$I_q = 1/2 (I_0 - E_0/Z_s) e^{q\tau} + 1/2 (I_0 + E_0/Z_s) e^{-q\tau} \quad (19)$$

$$E_q = 1/2 (E_0 - Z_s I_0) e^{q\tau} + 1/2 (E_0 + Z_s I_0) e^{-q\tau} \quad (20)$$

Represent the real and imaginary parts of τ by h and k respectively so that

$$\tau = h + jk \quad (21)$$

Equations (19) and (20) may now be written in two alternate forms, one involving the trigonometric functions and the other involving the hyperbolic functions.

The trigonometric forms are:

$$I_q = 1/2 (I_0 + E_0/Z_s) \epsilon^{-hq} (\cos kq - j \sin kq) + 1/2 (I_0 - E_0/Z_s) \epsilon^{hq} (\cos kq + j \sin kq) \quad (22)$$

$$E_q = 1/2 (E_0 + Z_s I_0) \epsilon^{-hq} (\cos kq - j \sin kq) + 1/2 (E_0 - Z_s I_0) \epsilon^{hq} (\cos kq + j \sin kq) \quad (23)$$

The hyperbolic forms are:

$$I_q = I_0 \cosh q\tau - E_0/Z_s \sinh q\tau \quad (24)$$

$$E_q = E_0 \cosh q\tau - Z_s I_0 \sinh q\tau \quad (25)$$

(5) *The Current and Voltage of Any Circuit in Terms of the Initial Voltage and the Terminating Impedance.* For some purposes it is useful to have the equations for current and voltage in terms of the sending end voltage and the terminating or load impedance. We next proceed to write these equations in terms of these constants.

The current in the end or n th section is:

$$I_n = I_0 \cosh n\tau - (E_0/Z_s) \sinh n\tau \quad (26)$$

The voltage in the n th section or across the terminating impedance is:

$$E_n = E_0 \cosh n\tau - Z_s I_0 \sinh n\tau \quad (27)$$

Also

$$Z_n I_n = E_n \quad (28)$$

From (26), (27) and (28) we obtain:

$$I_0 = E_0 \frac{\cosh n\tau + Z_n/Z_s \sinh n\tau}{Z_n \cosh n\tau + Z_s \sinh n\tau} \quad (29)$$

In (29) the reciprocal of the quantity multiplying E_0 is the impedance of the string of circuits looking into the generator end of the line. We represent this impedance by Z_L . That is:

$$Z_L = \frac{Z_n \cosh n\tau + Z_s \sinh n\tau}{\cosh n\tau + (Z_n/Z_s) \sinh n\tau} \quad (30)$$

And

$$I_0 = E/Z_L \quad (31)$$

Equations (22) and (23) may now be written:

$$I_q = 1/2 E_0 (1/Z_L + 1/Z_s) \epsilon^{-hq} (\cos kq - j \sin kq) + 1/2 E_0 (1/Z_L - 1/Z_s) \epsilon^{hq} (\cos kq + j \sin kq) \quad (32)$$

$$E_q = 1/2 E_0 (1 + Z_s/Z_L) \epsilon^{-hq} (\cos kq - j \sin kq) + 1/2 E_0 (1 - Z_s/Z_L) \epsilon^{hq} (\cos kq + j \sin kq) \quad (33)$$

Equations (24) and (25) may now be written

$$I_q = E_0 (1/Z_L \cosh q\tau - 1/Z_s \sinh q\tau) \quad (34)$$

$$E_q = E_0 (\cosh q\tau - (Z_s/Z_L) \sinh q\tau) \quad (35)$$

(6) *Comparison of the Equation with the Equation for the Smooth Line.* The equations which have been written down for current and voltage in the coupled circuit chain are identical in form with the equations for the current and voltage at any point of a long line with uniformly distributed constants. Thus equations (22), (23), (24) and (25) apply identically to the line

with uniformly distributed constants. However the expressions for Z_s and τ are different for the smooth line than for the coupled circuit chain. The most striking and fundamental difference occurs in the propagation constants for the two cases. For the smooth line the propagation constant is an algebraic function of the line constants, while for the coupled circuit chain the propagation constant is a transcendental function of the circuit constants. It will be shown later that this difference portrays the difference in the characteristics of the two types of systems. In the equation for the coupled circuit chain, q is a positive integer. For the smooth line q need not be an integer.

(7) *Conditions under which the Reflected Wave Disappears.* In equations (22) and (23) the first terms decrease as the circuit under consideration recedes from the generator end of the chain. In the case of the smooth line this term has been called the main wave of current, and voltage respectively. The second term of each of these equations increases in magnitude as the circuit under consideration recedes from the generator end. In long line theory these terms have been called the reflected waves. This terminology is both useful and convenient and will be adopted in the discussion of the coupled circuit chain. In the case of the smooth line the reflected wave can be made to disappear in two ways, first by making the line very long, second by terminating in an impedance equal to the characteristic impedance of the line. We proceed to show that if these same conditions are fulfilled, the reflected waves disappear from the equation for current and voltage in any circuit of the coupled circuit chain.

In equation (30), which relate Z_L to the circuit constants, divide both numerator and denominator by $\cosh n\tau$. This gives

$$Z_L = \frac{Z_n + Z_s \tanh n\tau}{1 + (Z_n/Z_s) \tanh n\tau} \quad (36)$$

$$\lim_{n \rightarrow \infty} Z_L = Z_s \quad (36)$$

So that for a very great number of circuits in the chain $E_0/Z_s = I_0$; $I_0 Z_s = E_0$ and the terms representing the reflected wave disappears from the equations for current and voltage.

Now consider the chain to be terminated by an impedance equal to the characteristic impedance of the chain. That is, let $Z_n = Z_s$.

Then it can readily be seen from equation (30) or (36) that $Z_L = Z_{sL}$ and the reflected wave is again absent.

Thus, when the chain is again made up of many circuits, or when it is terminated in an impedance equal to its characteristic impedance, the impedance looking into the chain is equal to the characteristic impedance and the terms representing the reflected wave are absent from the equations for current and

voltage. The current and voltage in the q th circuit are then given by the following simple equation.

$$I_q = I_0 e^{-q\tau} \quad (37)$$

$$E_q = E_0 e^{-q\tau} \quad (38)$$

$$I_q = I_0 e^{-hq} (\cos kq - j \sin kq) \quad (39)$$

$$E_q = E_0 e^{-hq} (\cos kq - j \sin kq) \quad (40)$$

(8) *The Attenuation Constant and the Wave Length Constant.* In the equation for current and voltage in the q th circuit of the chain of coupled circuits, the propagation constant τ is in general a complex number. We have represented τ by $h + jk$. Now consider the general equation for current or voltage. If we confine our attention to the main wave alone or to the reflected wave alone, then equations (22) and (23) show that h affects the amplitude of the wave without affecting its phase position. For this reason it is called the attenuation constant. k , on the other hand, affects only the phase position and in a number of circuits such that $kq = 2\pi$ the phase of the current in either the main or reflected wave shifts through 360 deg., or when we pass over a number of circuits q_w given by

$$q_w = \frac{2\pi}{k} \quad (41)$$

We have gone the equivalent of one wave length on a smooth line. For this reason k is called the wave length constant.

The propagation constant τ has already been evaluated in terms of the circuit constants. For many purposes it is convenient to evaluate h and k separately in terms of these constants.

From equation (8) we have

$$\cosh \tau = \cosh (h + jk) = -\frac{Z_c}{2Z_m} \quad (8)$$

$$\text{Let } Z_c/Z_m = u + jv = \gamma/\phi \quad (42)$$

Expanding (8)

$$\cosh (h) \cos (k) + j \sinh (h) \sin (k) = -\frac{u + jv}{2} \quad (43)$$

Since h and k are assumed real, $\sinh h$, $\cosh h$, $\sin k$, and $\cos k$ are all real. Equating real and imaginary parts there results:

$$\left. \begin{aligned} \cosh (h) \cos (k) &= -u/2 \\ \sinh (h) \sin (k) &= -v/2 \end{aligned} \right\} \quad (44)$$

Squaring the equations (44)

$$\left. \begin{aligned} \cosh^2 h \cos^2 k &= u^2/4 \\ \sinh^2 h \sin^2 k &= v^2/4 \end{aligned} \right\} \quad (45)$$

$$(\cosh^2 h - 1)(1 - \cos^2 k) = v^2/4 \quad (46)$$

$$\cos^2 k = 1 - \frac{v^2}{4(\cosh^2 h - 1)} \quad (47)$$

$$(\cosh^2 h) \left[1 - \frac{v^2}{4(\cosh^2 h - 1)} \right] = u^2/4 \quad (48)$$

$$\cosh^4 h - (\cosh^2 h) \left[1 + \frac{u^2 + v^2}{4} \right] = -u^2/4 \quad (49)$$

$$\cosh (h) = \left[\frac{1}{2} \left\{ \left(\frac{u^2 + v^2}{4} + 1 \right) + \sqrt{\left(\frac{u^2 + v^2}{4} + 1 \right)^2 - u^2} \right\} \right]^{1/2} \quad (50)$$

$$\cosh (h) = \left[1/2 \left\{ (\gamma^2/4 + 1) + \sqrt{(\gamma^2/4 + 1)^2 - \gamma^2 \cos^2 \phi} \right\} \right]^{1/2} \quad (51)$$

In like manner we obtain the relations

$$\cos k = \frac{-u}{\sqrt{u^2}} \left[\frac{1}{2} \left\{ \left(\frac{u^2 + v^2}{4} + 1 \right) - \sqrt{\left(\frac{u^2 + v^2}{4} + 1 \right)^2 - u^2} \right\} \right]^{1/2} \quad (52)$$

$$\cos k = \frac{-u}{\sqrt{u^2}} \left[\frac{1}{2} \left\{ \left(\frac{\gamma^2}{4} + 1 \right) - \sqrt{\left(\frac{\gamma^2}{4} + 1 \right)^2 - \gamma^2 \cos^2 \phi} \right\} \right]^{1/2} \quad (53)$$

Equations (52) and (53) do not determine the sign (or the quadrant) of k . If the sign of k is determined so as to satisfy the relation:

$$\sin k = \frac{-v}{2 \sinh (h)} \quad (53a)$$

then equations (50), (51), (52) and (53) always give real values to h and k which satisfy equations (41). The term $-u/\sqrt{u^2}$ is introduced into equations (52) and (53) so as to make $\cos k$ change sign with u as it must in order that equations (41) may be satisfied.

III. SELECTIVE PROPERTIES OF THE COUPLED CIRCUIT CHAIN

(9) *General Attenuation Characteristics.* Fig. 2 represents a chain of coupled circuits terminated by an impedance equal to Z_c so as to eliminate the reflected wave. The current in the q th circuit then is given by equation,

$$I_q = I_0 e^{-q\tau} \quad (37)$$

or

$$I_q = I_0 e^{-hq} (\cos kq - j \sin kq) \quad (38)$$

Where

$$\cosh \tau = -\frac{Z_c}{2Z_m} = -1/2(u + jv) \quad (4)$$

Let us now define an ideal filter as one built up of coils and condensers in which no energy dissipation takes place. Let the circuit under consideration be an ideal filter. Then Z_c and Z_m are both pure imaginary quantities and Z_c/Z_m is a real number, that is, v is equal to zero. For the ideal case then:

$$\cosh \tau = -\frac{Z_c}{2Z_m} = -u/2$$

where u is a real number. For any particular structure Z_c/Z_m is a function of the frequency of the applied

voltage and therefore also is a function of the frequency of the current being transmitted.

If $Z_c/Z_m < -2$ then $\cosh \tau > 1$ and τ is a positive real number; that is h has some positive value and $k = 0$. Thus currents having frequencies that make $Z_c/Z_m < -2$ decrease in magnitude but retain the same phase position as the circuit under consideration recedes from the generator end of the chain.

If $Z_c/Z_m > 2$ then $\cosh \tau$ is a negative number less than -1 . Under these conditions $h \neq 0$, $K = \pi$. Thus currents having frequencies that make $Z_c/Z_m > 2$ decrease in magnitude as the circuit under consideration recedes from the generator end of the string. There is also a phase shift of 180 deg. in passing from one circuit to the next adjacent circuit. If $-2 < Z_c/Z_m < 2$ then $\cosh \tau$ is a real number which in absolute value is less than unity. Under these conditions h is zero and k is, in general, different from zero. Thus currents having frequencies that give values of Z_c/Z_m that lie between -2 and $+2$ are transmitted without diminution through the chain. The frequencies that give to Z_c/Z_m the value plus or minus 2 for the idealized filter will be called the cut-off frequencies. The frequencies that give to Z_c/Z_m values between -2 and

FIG. 2

$+2$ will be called the transmitted band of frequencies. Frequencies that cause Z_c/Z_m to take the values outside the range -2 to $+2$, are said to be in region of attenuation or in the attenuated region.

It is to be noted that the attenuation characteristics described above are independent of any power loss in the filter network as the assumption was made that the coils and condensers used in building up the network were free from power losses. The characteristics come about solely through complex interaction of one circuit on the other. When particular types of structure are considered it will be shown that resistance causes attenuation in the transmitted region and lowers the attenuation in the attenuated region. We can, however, approach very near to the characteristic of the ideal filter by making the losses in coils and condensers as low as feasible.

(10) *General Wave Length Constant or Phase Shift Characteristics.* The general phase shift characteristics are most easily obtained from the general relation of equation (8).

$$\cosh \tau = \cosh (h + jk) = \frac{Z_c}{-2Z_m} = -\frac{u + jv}{2}$$

In the ideal filter we have shown that v is always zero, so for the ideal structure we may write $\cosh (h + jk) = -u/2$. When $u < -2$, τ is real and $k = 0$.

When $u > -2$, but less than $+2$, τ is a pure imaginary and as u varies from -2 to $+2$, k varies from 0 to π . That is within the transmitted band k varies from 0 at one cut-off frequency to π at the other cut-off frequency. As the frequency approaches one of the cut-off points from the attenuated region u is continually less than -2 and k is continually zero, as the other cut-off frequency is approached from the attenuated region u is continually greater than $+2$ and k continually equals π .

Sections (9) and (10) taken together give some very interesting properties of the ideal coupled circuit structures. In the attenuated regions, the phase shift or wave length constant remains at a constant value 0 or π , while the attenuation constant continually, takes on different values. For all frequencies within the transmitted band, the attenuation constant remains constant while the phase shift constant varies from zero to π .

(11) *General Impedance Characteristics.* Consider again the circuit of Fig. 2. Let the problem be that of transferring maximum power at frequencies within the transmitted band or within a portion of the transmitted band from the generator to a utilization device terminating the filter. Let the generator impedance be represented by Z_0 . For the theory of section (9) to apply the utilization device must have the impedance Z_s or must be corrected to Z_s by means of a suitable transformer. It will be shown later that Z_s may be a pure resistance.

Let the terminating impedance Z_n be a pure resistance R_n . If R_n were directly across the generator terminals it would receive maximum power when $Z_0 = R_n$, or was corrected to R_n by means of a transformer. If the termination is such that $R_n = Z_s$, then the theory of section (9) applies and the resistance R_n receives the same power as though it were across the generator terminals. Therefore, for maximum power delivery from the generator to the terminating device, the system should be so designed that $Z_0 = R_n = Z_s$.

If Z_n and Z_0 are to be fixed resistances then in general we can satisfy the above relation for only one particular frequency within the transmitted band as Z_s , although it may be made a pure resistance within the transmitted band, varies with the frequency. The detailed manner in which it varies with the frequency will have to be taken up for each type of structure considered. In general, however, it may be stated that the impedance curve is fairly flat for quite a range of frequencies within the transmitted band, but falls to zero at the cut-off points. In the consideration of special types of structure it will be shown that this change in characteristic impedance has the effect of introducing a loss in the transmitted band. Over the greater share of the transmitted band this loss may be made small but at the cut-off points it may have an appreciable value.

(12) *Filters with Dissipation in Coils and Condensers.* In the discussion thus far contained in Part III it has been assumed that the coils and condensers used

in building the filter did not dissipate energy. This assumption insured that the ratio of the circuitual to the transfer impedance should be a real quantity. This in turn leads to the sharp breaks in the characteristics of the attenuation and phase shift constants described in sections (9) and (10). In any real filter both coils and condensers dissipate energy. For any real filter then the impedance ratio Z_c/Z_m is in general a complex number and the ideal filter theory does not rigorously apply. We can, however, approximate the ideal filter by using coils and condensers in which the ratio of resistance to reactance is small. We would expect the widest divergence between the characteristic of the ideal filter and the real filter at those points where the ideal filter characteristic takes a sudden break, namely at the cut-off points. This expectation will be verified when the actual characteristics of some particular types of structures are given.

IV. APPLICATION OF THE GENERAL THEORY TO A FILTER BUILT UP OF SIMPLE SERIES CIRCUITS MAGNETICALLY COUPLED TOGETHER

(13) *Conventions and General Method of Handling the Problem.* Before starting the discussion of particular types of filters, it will be of advantage to give a general survey of the method to be employed in treating the selective properties of these systems. The method has been employed by telephone engineers for some time in the discussion of transmission through all types of networks.

In section (11) it was shown that maximum power was delivered to the filter when the filter was so designed that its characteristic impedance was equal to the generator impedance which was taken to be a pure resistance, or was connected to the generator impedance by means of a suitable transformer. In the ideal filter within the transmitted band this power is transmitted undiminished to a utilization resistance if this resistance has a value equal to the characteristic impedance, Z_n , of the filter. Under these conditions we would say that the loss through the filter, or attenuation of the filter is zero because the power delivered to the utilization device is the same as though this device were connected directly across the generator terminals.

Now since our utilization devices can always be reduced to equivalent resistance it is obvious that instead of discussing power ratios, we may discuss current ratios. That is in order to obtain the loss occasioned by the filter it is sufficient to obtain the ratio of the current delivered to the utilization device when placed across the generator terminals to the current delivered to the device with the filter interposed between the generator and the utilization device. Let the current with the filter interposed be I_a and let the current delivered with the utilization resistance across the generator be I_0 . Then the ratio I_a/I_0 gives the effect of interposing the filter. Instead of using this ratio it is more convenient to use the natural logarithm

of the ratio. Then in the system to be used the loss will be one attenuation unit when the natural logarithm of the ratio of the current with the utilization device across the generator terminals to the current in the utilization device with the filter interposed between it and the generator is unity. The convenience and application of this unit will become apparent as the discussion proceeds. As an example of its usefulness however, consider the following.

A filter chain is terminated so that the reflected wave is absent. The impedances are such that the generator delivers maximum power to the filter. The current in any section of the filter then is:

$$I_a = I_0 e^{-qr}$$

$$|I_a| = |I_0| e^{-hq}$$

But I_0 is also the current which would flow if the terminating impedance were across the generator terminals, and we have,

$$|I_a'/I_a| = e^{qh}$$

$$\log_e |I_a'/I_a| = qh$$

Or the attenuation per section is h attenuation units. For q sections it is hq attenuation units.

(14) *Chain of Simple Series Circuits Magnetically Coupled. Ideal Case. (a) Cut-off Points.* The general theory thus far presented is very general and

FIG. 3

applies to all chain systems built up of identical circuits associated in such a way that the impedances of the system can be broken up into circuitual impedances and transfer impedances. The illustrations which follow, however, give rise to filter systems which in general cannot be broken up into series and shunt elements.

As a first application of the theory consider the system shown by Fig. 3. This system obviously fulfills the conditions of the general theory. For the purpose of synthetically building up filter systems it is convenient to think of Fig. 3 as made of elements, as shown in Fig. 4. Each of these elements will be called a filter section. Fig. 4 represents a two section filter.

We will first assume that Fig. 4 represents an ideal filter; that is, a filter in which the coils and condensers do not dissipate energy. The circuitual impedance is,

$$Z_c = j \left(\omega L_0 - \frac{1}{\omega C_0} \right) \quad (54)$$

The mutual or transfer impedance is:

$$Z_m = j \omega M$$

$$\text{Let } M = \frac{K_0 L_0}{2}; \quad |K_0| < 1$$

K_0 may be positive or negative.
Then,

$$Z_m = \frac{j \omega L_0 K_0}{2} \quad (55)$$

$$Z_c/Z_m = \frac{2 \left(\omega L_0 - \frac{1}{\omega C_0} \right)}{\omega L_0 K_0} \quad (56)$$

The angular velocities corresponding to the cut-off frequencies are such as to make,

$$Z_c/Z_m = \frac{2 \left(\omega L_0 - \frac{1}{\omega C_0} \right)}{\omega L_0 K_0} = \pm 2 \quad (31)$$

$$\omega L_0 - \frac{1}{\omega C_0} = \pm K_0 \omega L_0$$

The cut-off angular velocities are,

$$\omega_A = \sqrt{\frac{1}{L_0 C_0 (1 - K_0)}} = \omega_{r0} \sqrt{\frac{1}{1 - K_0}} \quad (57)$$

$$\omega_B = \left(\sqrt{\frac{1}{1 + K_0}} \right) \omega_{r0} \quad (58)$$

Where ω_{r0} is defined by the equation

$$\omega_{r0} = \frac{1}{\sqrt{L_0 C_0}} \quad (59)$$

It is interesting to note that the cut-off angular velocities are given by the same equation that give the natural angular velocities of two simple series circuits magnetically coupled together.

(b) *Attenuation Characteristics of the Ideal Filter.*
For the ideal filter it has been shown that the propagation constant is given by the relation,

$$\cosh \tau = -\frac{Z_c}{2 Z_m} = -u/2 - j0 \quad (8)$$

For the structure under consideration this gives

$$\cosh (\tau = h + jk) = (1/K_0) [(\omega_{r0}/\omega)^2 - 1] \quad (60)$$

At this point we are chiefly interested in the general shape of the attenuation curve; that is, in the general shape of the curve which has values of h for ordinates and angular velocity or frequency for abscissa. Within the transmitted band, that is for values of ω lying between ω_B and ω_A , the cut-off angular velocities, h is zero.

When $\omega = 0$, $\cosh (h + jk) = \infty$ and $h = \infty$.
When $\omega = \infty$, $\cosh (h + jk) = -1/K_0$. For the

ideal filter equation (50) gives $\cosh h = \pm \frac{u}{2}$; $h = \cosh^{-1} (|u/2|)$

$$\frac{dh}{d\omega} = \frac{dh}{du} \frac{du}{d\omega} = \frac{\pm 2 \omega_{r0}^2}{\omega K_0 \sqrt{(1/K_0)^2 (\omega_{r0}^2 - \omega^2)^2 - \omega^4}}$$

$$\text{When } \omega = 0, \left| \frac{dh}{d\omega} \right| = \infty$$

$$\text{When } \omega = \infty \text{ then } \frac{dh}{d\omega} = 0$$

$$\text{When } \omega = \omega_A = \omega_{r0} \sqrt{\frac{1}{1 - K_0}}; \quad \frac{dh}{d\omega} = \infty$$

$$\text{When } \omega = \omega_B = \omega_{r0} \sqrt{\frac{1}{1 + K_0}}; \quad \left| \frac{dh}{d\omega} \right| = \infty$$

The general attenuation characteristic then has a verticle tangent at $\omega = 0$ and becomes great without limit as $\omega \rightarrow 0$. As ω is increased from zero the slope remains finite and different from zero until $\omega = \omega_B$; here the curve has another verticle tangent and h takes the value zero and remains zero until $\omega = \omega_A$.

FIG. 4

At $\omega = \omega_A$ the curve has another verticle tangent and as the frequency becomes great without limit the value of h approaches the value $\cosh^{-1} (1/K_0)$. The general attenuation characteristic is, therefore, as shown by the sketch of Fig. 5.

When ω_A and ω_B are both finite the attenuation constant of the ideal filter for angular velocities lying between ω_A and ω_B is zero and the structure is called a band pass filter.

If $K_0 = 1$, $\omega_A = \infty$ and the attenuation constant is zero for all angular velocities above ω_B and the filter is called a high pass filter.

FIG. 5

(c) *Phase Shift Characteristics of the Ideal Filter.*
The manner in which the phase shift or wave length constant varies with the frequency can most readily be obtained by using the equation:

$$\cosh h \cos k = -u/2 \quad (45a)$$

$$\sinh h \sin k = -v/2 = 0 \quad (45b)$$

Case I K_0 positive

From equation (56) we obtain:

$$Z_c/Z_m = u = 2/K_0 [1 - (\omega_{r0}/\omega)^2]$$

For values of ω less than the lower cut-off angular velocity u is negative and it has been shown that h is different from zero. $\sinh h$ is thus different from zero and to satisfy (45b), $\sin k$ must equal zero. The value of k must therefore be 0 or π . In equation (45a) $\cosh h$ is positive, u is negative, and therefore $\cos k$ must be positive. Therefore, for frequencies below the lower cut-off frequency, k must equal zero.

For values of ω greater than the upper cut-off angular velocity, $\sinh h$ is different from zero so that $\sin k$ must equal zero and k must equal 0 or $\pm \pi$. Now u is positive so also is $\cosh h$ so that $\cos k$ must be negative. $k = \pm \pi$.

When $\omega = \omega_{r0}$, $u = 0$ so that $\cos k = 0$, $k = \pm \pi/2$. $\sinh h$ is also zero so equation (45b) becomes:

$$\sin k \frac{-v = 0}{2 \sinh h = 0} \quad (61)$$

If resistance were allowed in the circuits:

$$\begin{aligned} Z_c/Z_m = u + jv &= 1/K_0 \left[\frac{a \pm j b}{j s} \right] \\ &= 1/K_0 [\pm b/s - j a/s] \end{aligned} \quad (61a)$$

(61a) shows that when K_0 is positive v is negative and that k must lie in the first or second quadrant. We then may assign values to k as follows. Below and including ω_B , $k = 0$. At ω_{r0} $k = \pi/2$. Including and above ω_A , $k = \pi$.

Inside the transmitted band of an ideal filter k is given by

$$k = \cos^{-1} 1/K_0 [(\omega_{r0}/\omega)^2 - 1] \quad (61b)$$

Taking the derivative with respect to ω , we obtain:

$$\left| \frac{dk}{d\omega} \right| = \frac{2 \omega_{r0}^2}{\omega \sqrt{K_0^2 \omega^4 - [\omega_{r0}^2 - \omega^2]^2}} \quad (61d)$$

$$\text{When } \omega = \omega_B \quad \text{then} \quad \left| \frac{dk}{d\omega} \right| = \infty$$

$$\text{When } \omega = \omega_A \quad \text{then} \quad \left| \frac{dk}{d\omega} \right| = \infty$$

The wave length constant-angular velocity curve thus has a verticle tangent at each cut-off point. The general shape of the curve for K_0 positive is given by the full line curve of Fig. 6.

Case II. K_0 negative.

The derivatives for this case are as given above for case I. For angular velocities below ω_B , $\sinh h$ is different from zero so $\sin k = 0$, $k = 0$ or $\pm \pi$. u is positive. So also is $\cosh h$ and therefore $\cos k$ must be negative. $k = \pm \pi$.

For values of ω greater than ω_A $\sinh h$ is different from zero so $\sin k$ must equal 0. $k = 0, \pm \pi$ or $\pm 2\pi$. u is negative, so $\cos k$ must be positive. $k = 0$ or $\pm 2\pi$.

When $\omega = \omega_{r0}$, u is zero and $\cos k$ is zero. $k = \pm \pi/2$. $\sin k$ is again indeterminate. However from (61a) when K_0 is negative, v is positive and we see that k must lie in the second or third quadrant. Then

k must equal $-\pi/2$. We then may assign values to k as follows: For ω equal to and less than ω_B , $k = -\pi$. For $\omega = \omega_{r0}$, $k = -\pi/2$. For ω equal to or greater than ω_A , $k = 0$.

The general shape of the wave length constant curve for K_0 negative is as given by the dotted curve of Fig. 6.

(d) *Characteristic Impedance of the Ideal Filter and Design Formula.* The characteristic impedance is given by the relation:

$$Z_s = \sqrt{Z_c^2/4 - Z_m^2} = \sqrt{(Z_c/2 - Z_m)(Z_c/2 + Z_m)} \quad (13)$$

For the idealized structure under consideration:

$$Z_c/2 - Z_m = 1/2 j \left[\omega L_0 (1 - K_0) - \frac{1}{\omega C_0} \right]$$

$$Z_c/2 + Z_m = 1/2 j \left[\omega L_0 (1 + K_0) - \frac{1}{\omega C_0} \right]$$

FIG. 6

$$\begin{aligned} Z_s^2 &= -1/4 \frac{1}{\omega^2 C_0^2} [\omega^2 L_0 C_0 (1 - K_0) \\ &\quad - 1] [\omega^2 L_0 C_0 (1 + K_0) - 1] \end{aligned} \quad (62)$$

$$\begin{aligned} Z_s^2 &= -1/4 \frac{1}{\omega^2 C_0^2} [(\omega/\omega_{r0})^2 \{ (\omega/\omega_{r0})^2 (1 \\ &\quad - K_0)^2 - 2 \} + 1] \end{aligned} \quad (63)$$

At this point it is well to pause and consider the manner in which the constants of the filter are to be fixed. ω_{r0} is fixed by the location of the band to be transmitted. K_0 is determined by the width of the band of frequencies to be transmitted. Within the transmitted band the filter should have an impedance which matches the generator and power receiving device. That is Z_s at some point within the transmitted band is fixed by the impedance of the devices between which the filter is to be placed. We choose to fix the impedance for the angular velocity ω_{r0} and we wish to determine L_0 and C_0 in such a way that at ω_{r0} , Z_s shall equal Z_0 . Upon applying this condition to equation (63), there results

$$Z_0^2 = -1/4 \frac{1}{\omega_{r0}^2 C_0^2} [-K_0^2] = 1/4 \frac{K_0^2}{\omega_{r0}^2 C_0^2} \quad (64)$$

$$Z_0 = \frac{K_0}{2 \omega C_0} \quad (65)$$

It is to be noted that Z_0 is a pure resistance. Since in general, as stated before, Z_0 is fixed by the conditions of the problem so (65) really determines C_0 in such a way that the filter shall have the impedance Z_0 . That is, C_0 is given by the design formula:

$$C_0 = \frac{|K_0|}{2 \omega_{r0} Z_0} \quad (66)$$

The inductance is determined by the relation:

$$\begin{aligned} \omega_{r0}^2 &= \frac{1}{L_0 C_0} \\ L_0 &= \frac{2 Z_0}{|K_0| \omega_{r0}} \end{aligned} \quad (67)$$

Upon substituting (66) in (63) there results

$$Z_s = Z_0 \sqrt{(\omega/\omega_{r0})^2 - 1/K_0^2 (\omega/\omega_{r0} - \omega_{r0}/\omega)^2} \quad (68)$$

For some discussions it is desirable to have Z_s in terms of one of the cut-off frequencies instead of K_0 . To obtain this relation we note that (57) solved for K_0 gives,

$$K_0 = \frac{\omega_A^2 - \omega_{r0}^2}{\omega_A^2} = \frac{\omega_{r0}^2 - \omega_B^2}{\omega_B^2} \quad (69)$$

When (69) is substituted in (68) there results:

$$Z_s = \frac{Z_0 \omega_A^2}{\omega_A^2 - \omega_{r0}^2} \sqrt{\omega^2/\omega_A^2 (\omega_A/\omega_{r0} - \omega_{r0}/\omega_A)^2 - (\omega/\omega_{r0} - \omega_{r0}/\omega)^2} \quad (70)$$

$$= \frac{Z_0 \omega_B^2}{\omega_{r0}^2 - \omega_B^2} \sqrt{\omega^2/\omega_B^2 (\omega_{r0}/\omega_B - \omega_B/\omega_{r0})^2 - (\omega/\omega_{r0} - \omega_{r0}/\omega)^2} \quad (71)$$

FIG. 7—CHARACTERISTIC IMPEDANCE FOR COUPLED CIRCUIT WAVE FILTER

Equation (70) and (71) show that in the ideal filter Z_s is real or is a pure resistance through the transmitted band. At the cut-off points Z_s falls to zero and outside the transmitted band it is a pure reactance. The curves of Fig. 7 give a more accurate picture of the manner in which the characteristic impedance varies with the frequency in the ideal filter. Only the part of the

curve for frequencies above the resonant frequency is plotted since in each case the other half is nearly a reflection in a line through the resonant frequency of the part plotted.

(e) *Actual Curves for the Attenuation and Phase Shift Constants.* We are now in a position to actually plot up some curves showing the manner in which the attenuation and phase shift constants of the simple magnetically coupled filter vary with the frequency of the current being transmitted. In order to make these curves more general, for abscissa we will use the

FIG. 8—ATTENUATION CONSTANT CURVES FOR IDEAL FILTER

ratio ω/ω_{r0} and the coupling coefficient or band width constant will be used as a parameter.

We have the relation:

$$Z_c/Z_m = \frac{2 \left(\omega L_0 - \frac{1}{\omega C_0} \right)}{\omega L_0 K_0} \quad (56)$$

This equation can be put in the form:

$$Z_c/Z_m = 2/K_0 [1 - (\omega_{r0}/\omega)^2] = u + jv \quad (72)$$

$$\cosh [\tau = h + jk] = 1/K_0 [(\omega_{r0}/\omega)^2 - 1] \quad (73)$$

Both h and k are readily obtained from (73) for the following reasons. For angular velocities below ω_B , k is zero so (73) gives h directly. Within the transmitted band h is zero so (73) gives k directly. For angular velocities above ω_A , $k = \pi$ so h is again readily obtained. Within the transmitted band it is more convenient to use the relation:

$$\cos k = 1/K_0 [(\omega_{r0}/\omega)^2 - 1] \quad (74)$$

for obtaining values of k .

Actual curves for h and k are given by Figs. (8) and (9).

(f) *Line Impedance Characteristics.* The line impedance is given by the equation:

$$Z_L = \frac{Z_n \cosh \tau n + Z_s \sinh \tau n}{\cosh n \tau + Z_n/Z_s \sinh n \tau} \quad (30)$$

In order to make the curves independent of the terminating impedance Z_n , the ratio of Z_L/Z_n will be

used as ordinates. Dividing both sides of (30) by Z_n we obtain:

$$Z_L/Z_n = \frac{\cosh n\tau + Z_s/Z_n \sinh n\tau}{\cosh n\tau + Z_n/Z_s \sinh n\tau} \quad (75)$$

The computation for Z_L/Z_n is straight forward until it is attempted to find the value of this ratio at a cut-off point. At the cut-off points $\sinh n\tau$ is zero, so also is Z_s . We have therefore in the denominator of (75) an indeterminate form $0/0$ to evaluate. We proceed to obtain the equation which gives the value of Z_L/Z_n at the cut-off points.

At a cut-off point $\tau = 0$ or $j\pi$. For either value of τ $\sinh n\tau = 0$. Now within the transmitted band of an ideal filter $\tau = jk$, and we have the relations:

$$\cosh n\tau = \cosh jnk = \cos nk$$

So that at a cut-off point (75) becomes:

$$(Z_L/Z_n)_{\omega_A \text{ or } \omega_B} = \frac{\cos nk}{\cos nk + Z_n \frac{\sinh n\tau}{Z_s}} \quad (76)$$

Now we have the relation:

$$\cosh \tau = \frac{-Z_c}{2Z_m}$$

So

$$\sinh \tau = \sqrt{\frac{Z_c^2}{4Z_m^2} - 1}$$

also

$$Z_s = \pm Z_m \sqrt{\frac{Z_c^2}{4Z_m^2} - 1} \quad (77)$$

$$Z_s = \pm Z_m \sinh \tau \quad (78)$$

The sign to be used with (78) must be such as to cause the real part of Z_s to be a real positive number. Now inside the transmitted band of an ideal filter $\tau = jk$, so we have:

$$\sinh \tau = \sinh jk = j \sin k$$

Also inside the transmitted band of an ideal filter Z_m is a pure imaginary or:

$$\begin{aligned} Z_m &= \pm j|Z_m| \\ Z_s &= \pm |Z_m| \sin k \end{aligned}$$

Now from (53a) the sign of k is opposite to the sign of v so within the transmitted band of an ideal filter we have:

$$Z_s = \frac{-v}{\sqrt{v^2}} |Z_m| \sin k \quad (79)$$

Also $\sinh n\tau = \sinh jnk = j \sin nk$

So that

$$\frac{\sinh n\tau}{Z_s} = \frac{j \sin nk}{\frac{-v}{\sqrt{v^2}} |Z_m| \sin k}$$

$$\text{Lim.}_{k=0 \text{ or } \pi} \frac{\sinh n\tau}{Z_s} = \frac{-v}{\sqrt{v^2}} \frac{j}{|Z_m|} \frac{n \cos nk}{\cos k} \quad (80)$$

$k = 0 \text{ or } \pi$

And equation (76) becomes

$$(Z_L/Z_n)_{\omega_A \text{ or } \omega_B} = \frac{1}{1 - j n (Z_n/|Z_m|) (v/\sqrt{v^2}) \cos k} ; \quad (k = 0 \text{ or } \pi) \quad (81)$$

Now equation (81) contains the term $v/\sqrt{v^2}$. Now this term was introduced solely to fix a sign and thus avoid the necessity of carrying a double sign. However in an ideal filter v is zero. We must therefore use the sign which v would give if some small resistance were in the filter coils. This sign is readily determined from physical considerations or from equations like (99) which are derived hereafter.

Equation (81) is general and applies to all types of coupled circuit wave filters. For the type of structure now under consideration it may be put in a form more convenient for use as follows:

$$|Z_m| = 1/2 \omega L_0 |K_0|$$

$$L_0 = \frac{2Z_0}{|K_0| \omega_{r0}}$$

$$|Z_m| = Z_0 \omega / \omega_{r0}$$

If the filter is terminated, as is usually the case, so that $Z_0 = Z_n$ then:

$$|Z_m| = Z_n \omega / \omega_{r0} \quad (82)$$

In the structure under consideration if loss were allowed in the coils we would have:

$$Z_c/Z_m = u + jv = \frac{a \pm jb}{jK_0 S}$$

$$u + jv = 1/K_0 \left[\frac{ja \pm b}{-s} \right] = 1/K_0 [\pm b/s - ja/s]$$

Or v has a sign opposite to K_0 . This result could also be obtained from equation (99). We then may write:

$$v/\sqrt{v^2} = \frac{-K_0}{\sqrt{K_0^2}} \quad (83)$$

Upon substituting (82) and (83) in (81) there results:

$$(Z_L/Z_n)_{\omega_A \text{ or } \omega_B} = \frac{1}{1 + j n (\omega/\omega_{r0}) (K_0/\sqrt{K_0^2}) \cos k} \quad (84)$$

This is the equation giving the values of Z_L/Z_n at the cut-off points of the simple filter under discussion.

In applying equation (75) to obtain values of Z_L/Z_n within the transmitted band it is well to note that for certain frequencies the value of this ratio can be obtained with very little calculation if curves for the ratio Z_s/Z_n and of k have already been plotted. These frequencies are those which make $\cosh n\tau$ equal to zero and those which make $\sinh n\tau$ equal to zero. When $\cosh n\tau = 0$ then:

$$Z_L/Z_n = (Z_s/Z_n)^2 \quad (85)$$

When $\sinh n\tau = 0$ then:

$$Z_L/Z_n = 1 \quad (86)$$

$\cosh n\tau$ is zero for those frequencies which cause $n\tau$ to equal $j p \pi/2$ where p is an odd integer. $\sinh$

$n\tau$ is zero for those frequencies which cause $n\tau$ to equal $j q \pi$ where q is a positive integer. These frequencies are readily found from curves like those of Fig. 9.

A line impedance curve for $K_0 = 0.0754$ and $n = 3$ is shown by Fig. 10, only the part of the curve for

FIG. 9—PHASE SHIFT OR WAVE LENGTH CONSTANT FOR IDEAL FILTER

frequencies above the resonant frequency is shown as the other part has the same general shape. This curve is flatter for a greater portion of the transmitted band than the curve giving the characteristic impedance for $K_0 = 0.0754$. A flat impedance curve is desirable in those cases where the filter is used in circuits in which impedance irregularities are undesirable.

FIG. 10—IDEAL FILTER LINE IMPEDANCE

(g) *Total Loss Characteristics of the Ideal Filter.* From equation (34) we have for the current in the q th section of a coupled circuit wave filter the relation:

$$I_q = E_0 [1/Z_L \cosh q\tau - 1/Z_s \sinh q\tau] \quad (34)$$

This equation gives the current in terms of the voltage of the first section. We wish I_q in terms of the

impressed voltage. The relation between E_0 and the impressed voltage is

$$E_0 = \frac{E Z_L}{Z_0 + Z_L} \quad (87)$$

$$I_q = \frac{E}{Z_0 + Z_L} [\cosh q\tau - Z_L/Z_s \sinh q\tau] \quad (88)$$

If the terminating impedance were across the generator terminals, the current delivered to it would be:

$$I_n' = \frac{E}{Z_0 + Z_n} \quad (89)$$

The ratio of the current delivered to the terminating impedance to the current which would be delivered to it if it were across the generator terminals is given by the equation:

$$I_n/I_n' = \frac{1 + Z_n/Z_0}{1 + Z_L/Z_0} [\cosh n\tau - Z_L/Z_s \sinh n\tau] \quad (90)$$

If, as is generally the case, $Z_n = Z_0$ then (90) becomes:

$$I_n/I_n' = \frac{2}{1 + Z_L/Z_0} [\cosh n\tau - Z_L/Z_s \sinh n\tau] \quad (91)$$

In accordance with the plan announced at the beginning of this section the effect of interposing the filter between the generator and terminating impedance will be specified by giving the loss in attenuation units which results from the introduction of the filter. This loss has been defined by the relation:

$$A = \log_e I_n'/I_n \quad (92)$$

The calculation of the current ratio I_n/I_n' is straight forward until a cut-off point is reached. At a cut-off point $\sinh n\tau$ is zero, so also is Z_s . This gives rise to the indeterminate form:

$$\frac{\sinh n\tau}{Z_s} = -0/0$$

This indeterminate form was encountered before and its value is given by equation (80). Upon substituting (80) in (91) and letting $\omega = \omega_A$ or ω_B we have:

$$(I_n/I_n')_{\omega=\omega_A \text{ or } \omega_B} = \frac{2 \cos nk}{1 + Z_L/Z_n} [1 + (v/\sqrt{v^2}) j n (Z_L/|Z_n|) \cos k] \quad (93)$$

$$k = 0 \text{ or } \pi$$

Equation (93) is a general equation applying to all types of ideal coupled circuit wave filters. For the simple filter under consideration (93) can be simplified by the use of equations (82) and (83). Then for the filter under consideration we may write:

$$(I_n/I_n')_{\omega=\omega_A \text{ or } \omega_B} = \frac{2 \cos nk}{1 + Z_L/Z_n} [1 - j n (Z_L/Z_n) (\omega_{r0}/\omega) (K_0/\sqrt{K_0^2}) \cos k] \quad (94)$$

$$k = 0 \text{ or } \pi$$

A total loss characteristic for frequencies lying above the resonant frequency is given by the curve of Fig. 11. This curve is for a three section filter for which $K_0 = +0.0754$. The circuit constants are such that at the resonant frequency $Z_0 = Z_s = Z_n$. This is of course the same filter for which curves of h , k , Z_s and Z_i have already been given.

A comparison of the curve of Fig. 11 with three times the ordinates of the attenuation constant curve for the same filter as given by Fig. 8 shows that, with the exception of frequencies in the vicinity of the cut-off frequency and for very large frequencies, the loss figured from the attenuation constant alone gives a very close approximation to the total loss occasioned by the introduction of the filter. This is a very important fact as it allows preliminary design of ideal filters to be based upon the attenuation constant alone.

The variation of the total loss curve from the total attenuation curve for frequencies much larger than the resonant frequency is evident when we remember that

FIG. 11—TOTAL LOSS CURVE FOR IDEAL FILTER

the attenuation constant curve approaches $\cosh^{-1}|1/K_0|$ as $f \rightarrow \infty$ whereas the total loss curve approaches ∞ as $f \rightarrow \infty$ due to the fact that the line impedance becomes infinite when the frequency becomes infinite.

The marked deviation of the total loss curve from the total attenuation curve for frequencies in the vicinity of the cut-off frequency is due to the fact that in this vicinity the characteristic impedance differs widely from the terminating impedance. This gives rise to a large reflected wave term in the current equation. The total loss through the filter is equal to the number of sections times the attenuation constant only when the reflected wave term is zero or very small compared to the main wave term.

(15) *Chain of Simple Series Circuits Magnetically Coupled. Dissipative Case.* (a) *General Statement and Scope of this Section.* Real filters differ from ideal filters in that the former always have some power losses in coils and condensers whereas the latter have not. The characteristics of the real filter can be made

to approach those of the ideal filter by making these losses as low as possible. The losses in condensers can be made negligible but it is more difficult to construct coils with negligible power losses. It is the purpose of this section to give briefly the characteristics of the filter built up of simple series circuits magnetically coupled together, in which the coils are assumed to have energy losses.

All of the general equations of part II apply to the dissipative filter and the greater share of the special forms of these equations developed in section (10) also apply as well to the dissipative filter as to the filter without dissipation.

(b) *Cut-off Points, Attenuation and Phase Shift Characteristics.* As was pointed out in section (12) a filter which has losses in its coils has no sharp cut-off points, but currents of some frequency are very freely transmitted while others are transmitted very poorly. Since the dissipative filter has no definite cut-off points, the cut-off points of the idealized filter will be taken as the cut-off points. It is well to note that in this case the loss may be considerable at the cut-off frequencies.

The total propagation constant is given by equation (8). This equation may be used for finding both the phase shift constant and the attenuation constant by making use of a table of complex hyperbolic functions. In most cases it is more convenient to use equations (50) and (52) for determining these constants. The first step is to obtain an expression for the impedance ratio Z_c/Z_m .

For most coils used in high-frequency work the effective resistance varies with the frequency. For small frequency ranges this variation may be assumed to be a straight line function and we may let

$$\frac{R}{\omega L} = d \quad (96)$$

Then for the structure under consideration,

$$Z_c = (d + j) \omega L_0 - \frac{j}{\omega C_0} \quad (97)$$

$$Z_m = j \omega L_0 K_0/2 \quad (98)$$

$$Z_c/Z_m = u + jv = 2/K_0 [1 - (\omega_{r0}/\omega)^2 - jd] \quad (99)$$

In order to obtain a picture of the characteristics of the dissipative filter and to be able to compare its characteristics with those of the ideal structure curves will be given for the following conditions:

$$K_0 = +0.0754 \quad d = 0.002,$$

Curve A of Fig. 12 gives the attenuation constant characteristic for frequencies above the resonant frequencies. A comparison of this curve with the corresponding curve of Fig. 8 shows that, with the exception of frequencies in the vicinity of the cut-off frequency, the attenuation constant for this dissipative filter is nearly the same as for the ideal filter. The dissipative filter, however, has an attenuation constant

different from zero in the transmitted band. The value of the attenuation constant within the transmitted band and the deviation of the attenuation constant curve for the dissipative filter from that for the ideal filter depends upon the value of d .

Curve B of Fig. 12 gives the phase shift constant for frequencies above the resonant frequency. This curve is practically the same as the one given by Fig. 9 for the corresponding ideal filter.

(c) *Characteristic Impedance and Line Impedance.* The characteristic impedance is given by the relation

$$Z_c = \sqrt{Z_0^2/4 - Z_m^2} \quad (13)$$

FIG. 12—PHASE SHIFT CONSTANT, ATTENUATION CONSTANT AND TOTAL LOSS CHARACTERISTICS FOR A DISSIPATIVE FILTER

If we use the design formulas as given by equations (66) and (67) we can write:

$$Z_m = 1/2 j \omega L_0 K_0 = \pm j Z_0 \omega / \omega_{r0} \quad (100)$$

$$Z_c = (j + d) \omega L_0 - \frac{j}{\omega C_0} = \frac{2 Z_0}{|K_0|} [d \omega / \omega_{r0} + j (\omega / \omega_{r0} - \omega_{r0} / \omega)] \quad (101)$$

The characteristic impedances for frequencies above the resonant frequency are given by curve A of Fig. 13. A comparison of this curve with the corresponding curve for the ideal filter, given by Fig. 7 shows that, for all frequencies except those in the vicinity of the cut-off frequency, the curves are nearly identical. The characteristic impedance of the ideal filter falls to zero at the cut-off point whereas in the real filter it has a value other than zero at the cut-off point. In the ideal filter the characteristic impedance is a pure resistance within the transmitted band and a pure reactance without the transmitted band. In the real filter the characteristic impedance has a very small phase angle over the greater share of the transmitted band. In the vicinity of the cut-off point this phase angle increases rapidly to 45 deg. at the cut-off point. Beyond the cut-off point the phase angle increases rapidly to 90 deg. The deviation from the ideal case of course depends upon the value of d . The line impedance is given for the real filter as well as for the ideal filter by equation (75).

The line impedance curve for a three section dissipative filter in which $K_0 = +0.0754$, $d = 0.002$, is given by curve B of Fig. 13. This curve differs but little from the corresponding curve for the ideal filter given by Fig. 10. The two curves of Fig. 13 give a good comparison of the characteristic impedance and the line impedance for a three section dissipative filter. The line impedance is flatter over a greater portion of the transmitted band than the characteristic impedance. For frequencies outside the transmitted band and slightly removed from the cut-off frequency the two curves coincide to within a fractional part of a per cent.

(d) *Total Loss Characteristic.* The total loss characteristic will again be computed by the use of equations (91) and (92). All of the terms entering into these equations have already been given by curves or can readily be found from the data given by the curves. The calculation of the current ratio by means of (91) is straightforward everywhere because for the real filter no indeterminate forms appear.

The total loss characteristic for the three section filter under consideration is given by curve C of Fig. 12, since n for this filter is three, the total loss curve has been plotted to a scale three times as small as that used in plotting the attenuation constant curve. This makes it possible to see directly how closely the total

FIG. 13—CHARACTERISTIC IMPEDANCE AND LINE IMPEDANCE FOR A DISSIPATIVE FILTER

loss is given by three times the attenuation constant. A comparison of curves A and C show that the loss computed on the basis of the attenuation constant alone is a very close approximation to the total loss. A comparison of curve C, Fig. 12, with the curve of Fig. 11 will show that the total loss curve for the ideal filter gives a close idea of the total loss in the real structure.

This section and the preceding one have shown that a very good idea of the selective properties of a filter may be obtained from a consideration of the attenuation constant curves for the corresponding ideal structure. Further, the loss curve of a filter network de-

signed in accordance with the formulas given is obtained very closely by multiplying the ordinates of the attenuation constant curve by the number of sections in the filter. These two facts aid very much in the design of filters which must meet preassigned requirements.

V. FILTERS BUILT UP OF SECTIONS HAVING DIFFERENT ATTENUATION CHARACTERISTICS

(16) *General Considerations of the Problem of Building a Filter of Different Types of Sections.* If we have a chain built up by joining together an infinite number of identical coupled circuit filter sections then it has been shown that the transmission loss between any two sections is equal to the attenuation constant times the number of sections which separate the two under consideration. This follows because the reflected wave term drops out of the current equation and the current is given by a simple exponential expression. In filters with a finite number of sections we approach this condition by terminating the filter in such a way that over the greater portion of the transmitted band the structure acts as though it were in its infinite chain.

Let us now consider a chain built up of an infinite number of coupled circuit filter sections, but let us not require that all the sections be identical. Let us require, however, that all types of sections have the same characteristic impedance at all frequencies.

The chain may be divided up into groups of identical sections as shown by Fig. 14. To any of the groups as the S th group we may apply our general equations which give the current in any section of the group in terms of the current in the first section of the group. The terminating impedance is the impedance looking into the $S + 1$ group of sections. Since the chain is infinite or terminated by an impedance equal to Z_c , this impedance is also equal to Z_c and the reflected wave term is absent from the equations applying to the S th group. The transmission loss through the group is therefore $h_s n$. Also the loss through group $S - 1$ is $n' h_{s-1}$ and so on. The total transmission loss between points A and B is $n' h_{s-1} + h_s n + n'' h_{s+1}$. From this it follows that the total transmission loss between any two sections is equal to the

FIG. 14

sum of the attenuation constants for all the sections separating the two under consideration.

That which has been said concerning the infinite chain also applies to the structure terminated by an impedance equal to the common characteristic impedance of the elements.

It follows from the above discussion that the problem of building up a filter of different types of sections is solved when we can so design the sections that the different types have the same characteristic impedance. In the sections which follow we will base the design of

two types of filter sections upon the design of the section discussed in part IV in such a way that all three types have the same characteristic impedance and therefore can be used together in building up filters.

In sections which follow, attenuation characteristics alone will be employed in giving examples of built up filters. This is justifiable because it has been shown that the loss computed from the attenuation constant alone gives a good idea of the total loss characteristics of a structure.

(17) *The Filter Element Derived from Two Simple Series Circuits with Electrostatic and Electromagnetic*

FIG. 15

Coupling Between Them. The filter element to be considered here is shown by Fig. 15. The mutual inductance between the circuits is given by:

$$M_1 = \frac{L_1 K_1}{2}$$

The mutual elastance is given by the relation

$$S_m = \frac{S_1 H_1}{2}$$

In accordance with the principles laid down in section (16) we proceed to determine design formulas for this type of section so that it will have the same characteristic impedance at all frequencies as the simple section discussed in part IV. In the discussion which is to follow, all constants referring to the simple type of section or basic section will bear the subscript 0 while those referring to the section of Fig. 15 will bear the subscript 1 .

The condition which we are to satisfy is stated by the equation:

$$Z_{s0} = \sqrt{Z_{c0}^2/4 - Z_{m0}^2} = Z_{s1} = \sqrt{Z_{c1}^2/4 - Z_{m1}^2} \quad (102)$$

Upon putting the values of Z_c and Z_m in (102) and squaring both sides there results:

$$\left. \begin{aligned} \omega^2 L_0^2 - \frac{2 L_0}{C_0} + \frac{1}{\omega^2 C_0^2} - \omega^2 K_0^2 L_0^2 \\ = \omega^2 L_1^2 - \frac{2 L_1}{C_1} + \frac{1}{\omega^2 C_1^2} \\ - \omega^2 L_1^2 K_1^2 + \frac{2 K_1 H_1 L_1}{C_1} \\ - \frac{H_1^2}{\omega^2 C_1^2} \end{aligned} \right\} \quad (103)$$

Since (103) is to hold for all angular velocities, we may equate coefficients of like powers of ω .

From the constant terms there results:

$$L_0/C_0 = L_1/C_1 (1 - K_1 H_1) \quad (104)$$

From the terms in ω^2 there results:

$$L_1^2 = L_0^2 \frac{1 - K_0^2}{1 - K_1^2} \quad (105)$$

From the terms in $1/\omega^2$ there results:

$$C_1^2 = C_0^2 (1 - H_1^2) \quad (106)$$

Upon substituting (105) and (106) in (104) there results:

$$\frac{(1 - K_1^2)(1 - H_1^2)}{1 - K_0^2} = (1 - K_1 H_1)^2 \quad (107)$$

Equations (105), (106) and (107) fix L_1 and C_1 and either H_1 or K_1 in terms of L_0 , C_0 and K_0 . The ratio of H_1/K_1 is arbitrary. The manner of choosing this ratio will be taken up along with the discussion of the general shape of the attenuation constant characteristics.

The attenuation constant is a function of the impedance ratio $Z_e/Z_m = u + jv$, so we proceed to determine this ratio for the filter, section under discussion:

$$\text{As before let } d = \frac{R}{\omega L}$$

Then

$$Z_e = (d + j) \omega L_1 - \frac{j}{\omega C_1}$$

$$Z_m = j/2 \left(\omega K_1 L_1 - \frac{H_1}{\omega C_1} \right)$$

$$Z_e/Z_m = u + jv = \frac{2[(\omega/\omega_{r1})^2 - 1 - jd(\omega/\omega_{r1})^2]}{(\omega/\omega_{r1})^2 K_1 - H_1} \quad (108)$$

Where

$$\omega_{r1} = \frac{1}{\sqrt{L_1 C_1}}$$

For the ideal filter in which $d = 0$ this becomes

$$u = \frac{2[(\omega/\omega_{r1})^2 - 1]}{(\omega/\omega_{r1})^2 K_1 - H_1} \quad (109)$$

The attenuation constant for the ideal filter is determined by the relation:

$$\cosh(h) = |u/2|$$

There are four cases depending upon the relative values of K_1 and H_1

Case I $H_1 = 0$

This is the case of the filter discussed in detail in part IV.

Case II $K_1 = 0$

This is the case of the filter section with electrostatic coupling only. The general shape of its attenuation constant characteristic will now be determined for the ideal filter.

$$\text{When } \omega = 0, \quad u = -2/H_1, \quad h = \cosh^{-1} \left(\frac{1}{H_1} \right)$$

When $\omega = \infty, \quad u = \infty$

$$h = \cosh^{-1} \infty = \infty$$

The attenuation constant characteristic for this section is then as shown by Fig. 16.

Case III

$$H_1 > K_1$$

$$\text{At } \omega = 0; \quad \cosh h = 1/H_1$$

$$\text{At } \omega = \infty; \quad \cosh h = 1/K_1$$

When $\omega/\omega_{r1} = \sqrt{H_1/K_1}$ $\cosh h = \infty$ and the at-

FIG. 16

tenuation constant is infinite. That is the ratio of H_1/K may be thought of as a design parameter which fixes the frequency at which infinite attenuation occurs.

The general shape of the attenuation characteristic for a section coming under Case III is shown by Fig. 17.

An actual attenuation constant curve for a dissipative filter coming under Case III is given by curve A of Fig. 20.

FIG. 17

Case IV. $H_1 < K_1$

Here again at $\omega = 0$ $\cosh h = 1/H_1$ at $\omega = \infty$ $\cosh h = 1/K_1$ at $\omega/\omega_{r1} = \sqrt{H_1/K_1}$; $\cosh h = \infty$.

The general shape of the attenuation constant for a filter section coming under case IV is shown by Fig. 18. The design of all four cases of the filter section shown by Fig. 15 has been based upon the design of Case I in such a way that at all frequencies the filters have the same characteristic impedance. Now at a

cut-off point the characteristic impedance for the ideal structure fall to zero and changes from a pure resistance to a pure reactance and this is the only place at which this occurs so the different sections having the same characteristic impedance will also have the same cut-off points. For the ideal filter section, shown by Fig. 15 and designed in accordance with the formulas given, the characteristic impedance and the cut-off points can be computed from the equations given in part IV.

The cut-off points can also be found by determining the value of ω in equation (109) which will cause u to equal ± 2 . These cut-off angular velocities are found to be

$$\left. \begin{aligned} \omega_{A \text{ or } B} &= \omega_{r1} \sqrt{\frac{1+H_1}{1+K_1}} \\ \omega_{A \text{ or } B} &= \omega_{r1} \sqrt{\frac{1-H_1}{1-K_1}} \end{aligned} \right\} \quad (110)$$

where $\omega_{r1} = \frac{1}{\sqrt{L_1 C_1}}$

FIG. 18

It can be shown that the ω_A and ω_B determined from (110) are the same as those determined from (57) and (58) by substituting in (110) value for $L_1 C_1$, H_1 and K_1 from equation (105), (106) and (107).

(18) *Examples Built-up Attenuation Characteristics and of the Use of the Design Formulas.* In order to give a picture of the manner in which attenuation characteristics may be built up, the curves of Figs. 19, 20 and 21 were plotted. Curve A of Fig. 19 is the attenuation constant characteristic for a section in which $H_1 = 0$, $K = K_0 = 0.0325$, $d = 0.001$. Curve B of Fig. 19 is the attenuation characteristic for a two section filter in which the first section is the one described above and section 2 has the following constants $H_1 = K_0 = 0.0325$, $K_1 = 0$, $d = 0.001$. This combination gives a symmetrical band pass filter; that is, the attenuation for $\omega = A$ is the same as the attenuation for $\omega = 1/A$. This combination has infinite attenuation at $\omega/\omega_{r0} = 0$ and $\omega/\omega_{r0} = \infty$. Curve A of Fig. 20 is the attenuation curve for a section in which

$K_0 = 0.0325$, $K_1 = 0.2859$, $H_1 = 0.3153$, $d = 0.001$. Curve B is an attenuation curve for a two section filter. One section has the constants given above. For the other section the values of H_1 and K_1 have been interchanged. This combination of sections gives a symmetrical band pass filter in which the points of

FIG. 19—ATTENUATION CURVES FOR BAND PASS WAVE FILTER

infinite attenuation have been brought in from ∞ and 0 to

$$\omega/\omega_{r1} = \sqrt{\frac{0.3153}{0.2859}} \text{ and } \omega/\omega_{r1} = \sqrt{\frac{0.2859}{0.3153}}$$

The curve of Fig. 21 is the attenuation characteristic of a three section filter obtained by adding a section for which $K_0 = 0.0325$, $K_1 = 0$, $H_2 = 0.0325$, $d = 0.001$ to the filter just described above.

FIG. 20—ATTENUATION CURVES FOR COUPLED CIRCUIT WAVE FILTERS

As an illustration of the use of the design formulas let us consider the following problem:

It is desired to introduce between a generator whose impedance is 600 ohms, and a power receiving device of 600 ohms, resistance, a filter having the following characteristics:

The filter shall pass frequencies from 29,700 ~ to

30,300 $\sim$ with as small a loss as possible. The variation in loss over this transmitted band not to exceed 0.2 of an attenuation unit. The loss at 31,000 $\sim$ and above and at 29,000 $\sim$ and below shall exceed 5 attenuation units. Required, the constants of the filter.

We will assume that the value of the ratio of resistance to reactance which it is possible to obtain in coils is 0.002. The resonant frequency, f_{r0} will be taken at

FIG. 21—ATTENUATION CURVE FOR COUPLED CIRCUIT WAVE FILTER

the center of the transmitted band, namely as 30,000 $\sim$. The theoretical cut-off points must be taken so as to be outside the band which it is desired to transmit as there is appreciable loss at the theoretical cut-off points. We will choose $f_A/f_{r0} = \omega_A/\omega_{r0}$ as 1.016. The value of K_1 is obtained from equation (57).

$$K_0 = 1 - (\omega_{r0}/\omega_A)^2 = 0.0325$$

We will first try a two section filter, one section having a point of infinite attenuation at $\omega_\infty/\omega_{r1} = 1.05$ and the other having a point of infinite attenuation at $\omega_\infty/\omega_{r1} = 1/1.05 = 0.952$. The value of the K , are then as follows:

For the first section,

$$\sqrt{H_1/K_1} = 1.05; H_1/K_1 = 1.105$$

Substituting this in equation (107) we obtain

$$K_1 = 0.2859$$

$$H_1 = 0.3153$$

For the second section we obtain in like manner,

$$K_2 = 0.3153$$

$$H_2 = 0.2859$$

The losses in this two section filter based upon the attenuation constants alone is given by curve B of Fig. 20. This filter does not quite meet the require-

ments. To this filter we will add a third section for which $\omega_\infty/\omega_{r1} = \infty$. For this section then $K_3 = 0$. Equation (107) gives H_3 as follows:

$$H_3 = K_0 = 0.0325$$

The loss through this three section filter based upon the attenuation constants alone is shown by the curve of Fig. 21. This filter meets the requirements. Its constants are found as follows:

C_0 is given by equation (66) as

$$C_0 = \frac{|K_0|}{2 \omega_{r0} Z_0}, \text{ where } Z_0 = 600$$

$$C_0 = 1.437 \times 10^{-10} \text{ farads}$$

L_0 is given by equation (67) as

$$L_0 = \frac{2 Z_0}{|K| \omega_{r0}} = 0.1958 \text{ henrys}$$

L_1 is given by equation (105) as

$$L_1 = L_0 \sqrt{\frac{1 - K_0^2}{1 - K_1^2}} = 0.204 \text{ henrys}$$

C_1 is given by equation (106) as

$$C_1 = C_0 \sqrt{1 - H_1^2} = 1.364 \times 10^{-10} \text{ farads}$$

L_2 is given by equation (105) as

$$L_2 = L_0 \sqrt{\frac{1 - K_0^2}{1 - K_1^2}} = 0.2062 \text{ henrys}$$

C_2 is given by equation (106) as

FIG. 22

$Z_0 = Z_n = 600 \text{ ohms}$	
$C_1 = 8.652 \times 10^{-10} \text{ farads}$	$L_1 = 0.102 \text{ henrys}$
$C_2 = 3.974 \times 10^{-10} \text{ "}$	$L_2 = 0.102 \text{ "}$
$C_3 = 1.958 \times 10^{-10} \text{ "}$	$L_3 = 0.1031 \text{ "}$
$C_4 = 3.974 \times 10^{-10} \text{ "}$	$L_4 = 0.201 \text{ "}$
$C_5 = 1.678 \times 10^{-10} \text{ "}$	$L_5 = 0.0979 \text{ "}$
$C_6 = 8.843 \times 10^{-10} \text{ "}$	$M_1 = 0.02916 \text{ "}$
$C_7 = 2.971 \times 10^{-10} \text{ "}$	$M_2 = 0.03251 \text{ "}$
$K_0 = 0.0325, K_1 = 0.2859, K_2 = 0.3153$	
$H_1 = 0.3153, H_2 = 0.2859, H_3 = 0.325$	
$\omega_a/\omega_{r0} = 1.016, \omega_{\infty 1}/\omega_{r0} = 1.05, \omega_{\infty 2}/\omega_{r0} = 0.952$	
$\omega_{r0} = (30,000) 2\pi, d = 0.001$	
Attenuation characteristics given by Fig. 21	

$$C_2 = C_0 \sqrt{1 - H_2^2} = 1.377 \times 10^{-10} \text{ farads}$$

L_3 is given by relation (105) as

$$L_3 = L_0 \sqrt{1 - K_0^2} = 0.1958 \text{ henrys}$$

C_3 is given by (106) as

$$C_3 = C_0 \sqrt{1 - H_3^2} = 1.437 \times 10^{-10} \text{ farads}$$

The filter goes together as shown by Fig. 21. After combining elements, the constants of the filter are shown by Fig. 22.

COMPILATION OF SYMBOLS

- γ Defined by $Z_c/Z_m = \gamma/\phi$
 C Stands for capacitance
 d Stands for the ratio of resistance to reactance of coils $= R/\omega L$
 E Stands for voltage
 e Represents the naperian base of logarithms
 f Represents frequency
 h Represents the attenuation constant
 H Represents the coefficient of electrostatic coupling
 I Represents current
 j Represents the rotative operator $\sqrt{-1}$
 k Represents the wave length or phase shift constant
 K Represents the coefficient of electromagnetic coupling
 L Represents self inductance
 M Represents mutual inductance
 R Represents resistance
 S Represents elastance
 S_m Represents mutual elastance
 τ Represents the propagation constant
 u Represents the real part of the ratio Z_c/Z_m
 v Represents the imaginary part of the ratio Z_c/Z_m
 ω Represents angular velocity
 ω_A & ω_B Represent cut-off angular velocities
 ω_{r0} Represents the resonant angular velocity
 ω_∞ Represents the angular velocity at which the attenuation becomes infinite
 Z_c Represents the circuitual impedance that is the impedance of each circuit when isolated from the chain
 Z_L Represents the line or chain impedance looking into the generator end of the chain
 Z_m Represents the mutual or transfer impedance
 Z_n Represents the terminating or load impedance
 Z_0 Represents the generator impedance
 Z_c Represents the characteristic impedance of the chain $= \sqrt{Z_c^2/4 - Z_m^2}$

Discussion

Kenneth S. Johnson: There are certain statements made in the Peters paper to which I wish to take exception and which, unless pointed out, I believe are likely to be misleading.

The coupling or mutual impedance, Z_m , is represented in the paper symbolically as a network with *two* pairs of terminals. Since, however, it introduces the same impedance into both adjacent sections and is completely defined by a single impedance, Z_m , it is actually only a network with *one* pair of terminals. Consequently with no loss of generality whatsoever Fig. 1 of the paper can be represented by the following sketch.

But since any network with only one pair of accessible terminals is always completely represented by a single impedance element the above sketch and hence Fig. 1 of the paper may be shown with complete generality by Fig. 2. Comparing this with one of Campbell's figures¹ it is evident that the two figures are exactly the same. It should be noted, however, that there is a difference in the method of designating the impedances. Although the Z_m of the Peters paper is exactly equal to the Z_2 of the Campbell paper, Campbell defines his Z_1 so that it includes only the series impedance component while Peters' Z_c com-

prises the series impedance plus twice the shunt impedance. That is

$$Z_c (\text{Peters}) = Z_1 + 2 Z_2 (\text{Campbell})$$

Evidently the two figures are identical. Either of them properly represents any periodic recurrent structure. We should understand, however, that Campbell's Z_1 and Z_2 or Peters' Z_c and Z_m (assuming one assigns to his work the broadest application) are symbolic and may not be actually realizable impedance elements as indicated. This is a commonplace to those familiar with electric circuit theory and its symbolism. Any of these impedances may be a complicated network in itself. The essential thing is that, as regards the structure in which it is inserted, it is a network with *one* pair of accessible terminals only.

However, if Mr. Peters prefers the symbolism of the "square

FIG. 1

box" to that of the equivalent "T" or "π" network the filter may be represented as shown in Fig. 3.

Each box represents a network with *two* pairs of terminals and is completely defined by three impedance parameters. The theory and formulas of the filter may then be developed in terms of these parameters² without explicit reference to the equivalent "T" network as is done by Zobel.³ This procedure, of course, gives no gain whatsoever in generality. Mr. Peters, evidently not appreciating the equivalence of the circuits noted above, makes the following statements in his paper.

"The conception of circuitual and transfer impedance as a broad basis for filter theory and the type of section to which the treatment leads directly are thought to be original."

"The general theory presented in the following sections is somewhat broader than that presented by Campbell and Wagner as it introduces, as a special case, the filter built up of series and shunt elements, as the shunt element may be considered as a coupling element."

FIG. 2

Evidently the forms discussed by Mr. Peters may be properly considered to be special cases of the Campbell treatment. In this connection reference to an article by Luschen and Krause⁴ is of interest. They, incidentally, also discuss in more or less detail the particular type of inductively coupled structure shown in Fig. 3 of Mr. Peters' paper.

In the next to the last paragraph on page 449 he states that "If Z_n and Z_0 are to be fixed resistance then in general we can satisfy the above relation for only *one* particular frequency within the transmitted band . . .". This statement is not, in general, true as may be seen by reference to Fig. 5 on page 18 of

1. See Fig. 4 in G. A. Campbell's paper on the "Physical Theory of the Electric Wave Filter," *Bell Technical Journal*, Vol. 1, No. 2, (Nov. 1922).

2. See "Cisoidal Oscillations" by G. A. Campbell. *TRANS. A. I. E. E.*, 1911, Vol. XXX, Part II.

3. "Theory and Design of Uniform and Composite Electric Wave Filters," *The Bell System Technical Journal*, January 1923, Page 32.

4. See Vol. 1, Third Issue (Nov. 1921), *Wissenschaftliche Veröffentlichungen aus dem Siemens-Konzern*.

the paper by Mr. Zobel which has already been referred to. In fact it is possible in certain types of band pass filters to satisfy the above relation for as many as *four* particular frequencies within the transmitting band.

A few sentences later we read that "In general . . . the impedance curve is fairly flat for quite a range of frequencies within the transmitted band but falls to zero at the cut-off points." The characteristic impedance of a large number of filters does become zero at the cut-off points but for practically an equally large number of filters it becomes of infinite value at one or more of the cut-off points.

With regard to the specific forms of wave filters discussed by Mr. Peters the type shown in Fig. 3 of the paper appears to have been investigated several times previously.⁵ Since two separate inductances coupled together by a mutual inductance are always replaceable by an equivalent "T" or "π" network each arm of which is an inductance, it is evident—as has already been pointed out by Luschen and Krause as well as by Zobel⁶—that the structure shown in Fig. 3 of Mr. Peters' paper is electrically equivalent to a structure of the series-shunt or "ladder" type whose series arms consist of an inductance in series with a capacity and whose shunt arms consist merely of an inductance. In a like manner the structure shown in Fig. 15 of Mr. Peters' paper is reducible by the same procedure to a structure of the ladder type whose series arms comprise an inductance and condenser in series and whose shunt arms are likewise comprised of an inductance in series with a condenser. Complete design formulas for these latter structures, which have been used commercially and which are equivalent to the ones which Mr. Peters has shown in Fig. 3 and 15, are given on page 42 (*V₁* and *VIII₁*) of Mr. Zobel's paper to which we have already referred.

On page 456, Mr. Peters states that " . . . with the exception of frequencies in the vicinity of the cut-off frequency and for very large frequencies the loss figured from the attenuation constant alone gives a very close approximation to the total loss occasioned by the introduction of the filter." It should be pointed out that this statement is not true for very low frequencies where the reflection effects in band pass wave filters are equally as large as they are for very high frequencies and consequently greatly increase the loss caused by the introduction of the filter.

The statement is also made at the top of the second column on page 456 "That the losses in condensers can be made negligible."

FIG. 3

This is never true with reference to paper condensers and is by no means true even with mica condensers, at relatively high frequencies. For example, the losses in the best mica condensers will approximate the losses assumed by Mr. Peters to exist in the coils *i. e.* the ratio of their resistance to their effective reactance is of the order of magnitude of 0.001. It should be pointed out however in this connection, that the value of 0.001 for "*d*," which is the value Mr. Peters has assumed in computing the curves shown in Figs. 19, 20 and 21, is very much smaller than has ever been encountered commercially so far as we know. To our knowledge coils with a value of "*d*" of 0.005 are about as efficient as have ever been commercially constructed. The effect of this greater amount of dissipation, is, of course, to increase the loss proportionally in the center of the transmitted band and to make the attenuation curves much more rounded near their cut-off frequencies.

5. See the article by Luschen and Krause previously referred to. See also K. W. Wagner's article on "Multiplex Telephony and Telegraphy with High Frequency Alternating Currents," *Elektrotechnische Zeitschrift*, August 14, 1911, Note 1 on page 395.

6. See paragraph 1 on page 30 of the paper already mentioned.

L. J. Peters: I greatly appreciate Mr. Johnson's discussion of my paper, first, because he has called attention to some points of which I was aware but stated rather loosely, and second, because he has called attention to some things of which I was not aware. However, in regard to the broadness and suggestiveness of the series—shunt impedance treatment as given by Campbell and others and the circuitual—transfer impedance treatment as given by myself, I would like to state clearly in what way I regard the latter treatment as being the broader. I agree with Mr. Johnson that either treatment can be used to design or to investigate all of the types of filter sections which we have in mind. I further agree that one treatment can be thrown over into the other by a suitable transformation of the equations. My contention is that the circuitual—transfer impedance terminology and view point is broader in its suggestiveness, at least

Class 1
FIG. 4Class 2
FIG. 5

to the average engineer, than the series-shunt impedance terminology. In order to state more clearly what I mean, I will designate as Class 1 those filters actually constructed as shown by Fig. 4, and as Class 2 those filters actually constructed as shown by Fig. 5. Then my contention is that the circuitual—transfer impedance terminology at once suggests filter sections of Class 1 and Class 2 whereas the series-shunt impedance terminology suggests to the average engineer only filters of Class 2. I infer that the series-shunt viewpoint did not immediately suggest filters of Class 1 even to those very familiar with the electrical equivalence of various kinds of networks, as Dr. Campbell's original patent specifications, to which I have referred in my paper, do show diagrams for the possible variations of Class 2 filters but show no diagrams even indirectly suggesting a Class 1 type of filter. Also the published works with which I was familiar at the time my paper was written did not suggest to me at least that filter sections of Class 1 had been considered.

In this connection I would like to point out that there is a vast difference between having enough general theoretical knowledge to cover a given phenomenon and the actual consciousness that the phenomenon exists. As an illustration of what I mean, consider the thermionic vacuum tube. Nearly every engineer and physicist who came into contact with the two element tube had enough electrodynamic theory to know that the interposition of the third element would convert the tube into a device having untold possibilities. Yet the third element was not put in for years after the discovery of the two element device, and even after it was inserted, the possibilities of the device developed slowly over a number of years. That is, a realization of the possibilities of the device came about only by stating the general electrodynamic theory in such a way as to specifically cover the applications. I claim that the circuitual—transfer treatment is broader than the series-shunt treatment because it does state filter theory in such a way as to specifically cover filters of both Class 1 and Class 2, whereas the series-shunt treatment does not.

Now besides the broader suggestiveness of the circuitual—transfer impedance viewpoint over that of the series-shunt impedance viewpoint, there is also a correspondingly greater broadness in its immediate applicability. Even though the sets of equations arrived at by the two treatments are equivalent in that one set may be transformed into the other, the set of equations which I have given apply directly to both Class 1 and Class 2 filters, whereas before the series-shunt equations can be used

to treat Class 1 filters, either the equations must be transformed into the form given in my paper or else the Class 1 network must be replaced by an electrically equivalent Class 2 network. That is, in order to use the series-shunt treatment to handle Class 1 networks, one must have in addition to the filter theory an insight into the possibilities of the replacement of one type of network by an electrically equivalent one. Under these conditions I believe that it would be customary to regard the circuitual-transfer impedance treatment as being

more general than the series-shunt impedance treatment.

Lest it be overlooked by some, I would like to call attention to the dates of the wave filter papers by Campbell and Zoebel referred to in Mr. Johnson's discussion. I do this, not to show that the filters of Class 1 were just recently considered by Mr. Johnson and his co-workers as Mr. Johnson has just sent me a memoranda from his files which shows that he considered this class of filter as early as 1919, but to call attention to the fact that these papers were not available when my paper was written.

The Automatic Train Control Problem

BY E. J. BLAKE

Associate, A. I. E. E.
Electrical Engineer, Gould Coupler Co.

Circumstances which make train control a pressing problem at the present time are mentioned. Certain desiderata are briefly discussed; the automatic control should act as a check on the proper exercise of manual control, not as a substitute; should conform to established safe signaling practises; should be designed for the severe conditions of railway operation; should not conflict with existing signals or otherwise introduce new hazards; should so far as possible conform to existing clearance lines; should not impede traffic; may be desired to exercise signal as well as control functions; may ultimately be desired for interlocking plants as well as main line tracks. Methods of transmitting and indication of track conditions to the train are described, (1) by intermittent mechanical and electric contact; (2) by intermittent induction through the use of permanent or electromagnets; (3) by continuous induction from the rails. Two general types of controlling action on the train are described, with some of their variations; (1) unconditional stop effective at a stop signal, with overlapping signal control, and (2) conditional stop effective at a caution signal. Relations between the type of controlling action and traffic capacity are discussed.

THE problem of mechanically enforcing observation and obedience of railway signals has attracted inventors and engineers for many years; but until very recent years railway officials have been inclined to view automatic train control as something rather Utopian; highly desirable no doubt, but too remote to command serious attention when the resources of the railroads were already taxed to provide other and more pressing improvements in the interest of safety; for example, extensions of existing signal systems and elimination of grade crossings. Within the last few years, however, a large number of disastrous wrecks attributed to disregard of signal indications have brought home the need for some effective check on the functioning of human, and therefore fallible engineers. The Interstate Commerce Commission has commented on the need with increasing emphasis, and finally has ordered automatic control installed on a large mileage of important lines. The train control problem thereby becomes so urgent that it is believed a brief review of the characteristics desired in automatic train control devices and of the broad features of some systems now available may have some general interest.

The roadside signal systems already installed on the principal railroads are adequate in so far as regards the detection and indication by visible signals of the presence of trains or other danger conditions along the track beyond the signal. The present demand is for an automatic device to bridge the gap between signals properly displayed, and trains properly controlled in accordance with the signal indications. The kernel of all modern roadside signal systems is the continuous

track circuit consisting of the track rails, extending through the length of the block, a source of low-volt d-c. or a-c. power at one end and a relay at the other end. So long as the track is unoccupied and the rail circuit intact, the relay is held closed by current passing through the rails from end to end of the block, and establishes local circuits to cause the clear, or safe signal indications to be displayed. But if the rail circuit is interrupted, or short-circuited by a train in the block, the relay is deprived of power and opens, and the signal reverts to its restrictive indication. Similarly, the kernel of the train control problem is the transmission to the train of an indication of conditions in one or more blocks ahead. Given an indication on the train capable of controlling a relay, almost any desired cycle of automatic operation can be established to control the train. The principal problem beyond the relay is to determine what operations are desired.

Before discussing any specific solution of the train control problem, it will be well to examine briefly some of the requirements or desiderata which constitute the conditions of the problem.

DESIRED CHARACTERISTICS

1. The primary function of automatic train control is, of course, to stop the train before it enters upon unsafe territory. But it is not necessary or desirable that it should interfere with manual control by the engineer, so long as that conforms to the requirements of safety. To substitute even a very perfect mechanical safeguard for human vigilance would be, to say the least, a questionable gain. Perhaps the mechanical

device would respond to the foreseen conditions for which it was designed with more than human certainty; but it could not act intelligently in response to unforeseen conditions. The real gain in safety is to be made by reinforcing the vigilance of the engineer, not by supplanting it. With an automatic control, acting as a second line of defense behind the engineer we have two independent and successive safeguards. Either one may fail, and doubtless will on rare occasions; but the chance that both will fail simultaneously is exceedingly remote.

The automatic apparatus, therefore, should not relieve the engineer of complete responsibility for the safe operation of the train. It should act as a continuous check on the proper exercise of that control, intervening to stop the trains automatically only after the engineer has had ample opportunity to act, and has failed. There is evidence to show that automatic control thus applied, tends to increase, and not relax, the vigilance of the engineer, because the automatic application of the brakes acts as an immediate tell tale if he ever passes a danger signal. It may be desirable as an aid to discipline to have the apparatus record each automatic brake application or preserve some evidence of it in the way of broken seals or the like.

2. The existing fixed signal systems have been developed to a very high degree of reliability in the course of a good many years. Prudence would dictate that the principles and practises which experience has shown to be safe for fixed signals should be followed so far as they are applicable in the installation of automatic control. The most fundamental of these practises is the so-called "closed circuit" rule, which requires that every "clear" or "proceed" indication be made dependent on the integrity of energized closed circuits, so that any interruption of the circuits or of the power supply will result in a danger indication. In practise, the rule is construed more broadly than this literal interpretation. Not only circuits, but every element of the system is so arranged that it is predisposed to the position or condition corresponding to a danger indication, and will return to that condition automatically upon failure of any part. In the construction of each element every precaution is taken to reduce to a minimum the chance that friction, insufficient clearance, residual magnetism, sticking of contacts or any other cause will bring about a failure to return to the danger indication, when de-energized. It is chiefly due to the rigid application of this rule that such failures as occur in signal systems are almost invariably failures on the safe side—false indications of danger, rather than false indications of safety.

3. Obviously the apparatus should be designed to stand the severe conditions of shock, dirt, weather, etc. that are incident to railway operation, and should not be put out of action by any weather conditions that permit trains to run.

4. The train control devices should not increase the hazards of operation in any respect. They should be free from insecure or dangerous parts, and in particular they should not impair the protection given by existing signal equipment; for regardless of the cab signaling features, that may be incorporated with the automatic control apparatus, railroad officials would be naturally and properly reluctant to abandon the known security they obtain from the existing signals before it has been conclusively established by experience that the new apparatus is at least as reliable as the old. Even if the old apparatus were to be abandoned, it would be highly desirable that the new and the old should cooperate without interference during the transition stage.

5. If possible, it is desirable to avoid conflict with established clearance lines. Where third rail has been installed for traction purposes, it has been necessary to reserve a zone exclusively for the third rail and the contact shoes, excluding from the reserved zone all other parts of equipment and roadway structures. The same thing can be accomplished for train control apparatus if it must be; but it is by no means so simple a matter as it sounds. Bridges, tunnels, station platforms and innumerable roadway structures have been built on the basis of existing clearance lines. Any change in the lines now involves many complications and much expense. The same is true of rolling stock. At least one electrified road has been obliged to gage every foreign freight car accepted for the third rail division, to check its clearance. The most available location for contact devices if used will probably be about the same as that adopted for traction third rails, when not used or reserved for the latter purpose. Third-rail lines will have to find some different location.

6. The automatic control should place no avoidable restriction on the traffic capacity of the road. An effective argument in favor of automatic roadside signals has been the fact that they "keep the trains moving" and increase the traffic capacity. It will be difficult to reconcile the railroads to automatic control if it is found to impede traffic in any noticeable degree. This is an interesting phase of the problem which will be discussed at more length later.

7. It may be desirable in some cases to enforce automatically, local speed restrictions, at curves for example, or heavy down grades, or a uniform speed restriction at all points.

8. The accidents which it is desired to prevent are due in some cases to negligence on the part of the engineers, but in other cases they are due to actual inability to distinguish and interpret the roadside signals correctly, because they are obscured by weather conditions or by steam from other trains or the like. In such cases a clear indication of the safety or danger of the track ahead, given within the engine cab, would enable the engineer himself to avoid danger. Such an

indication can be combined with the automatic control, in some cases at least, with comparatively little increase of complication or expense.

9. All of the foregoing has referred primarily to "block signaling" territory, *i. e.*, to main lines between terminals when the sole problem is to space trains at safe intervals; and the recent order of the Interstate Commerce Commission seems to be limited to this territory. But there is another very large portion of the total signaling of railways involved in interlocking plants where switches, derails and the like, as well as signals are controlled by an operator. There is no inherent reason to prevent at least a partial application of automatic control, or cab signals, or both in the interlocking as well as the block signal territory. But the need is less urgent, because speeds are low and signals are observed at shorter range. And the problems involved are more complex, because extensive net works of inter-related tracks are involved, and varied indications of routes and movements are required. Comparatively little thought has thus far been given to automatic train control in interlocking territory.

METHODS OF TRANSMITTING AN INDICATION TO THE TRAIN

The simplest system of automatic control and the one that has been used on the largest scale consists of an air valve hung on the car truck near the rail level, and stop arms operated in conjunction with the fixed signals. Whenever a stop signal is displayed, the stop arm is raised into the path of the air valve handle. If the train overruns the stop signal, the valve handle strikes the stop arm, and is knocked open, producing an emergency application of the brakes. This system has given excellent service on the subway and elevated lines where it has been employed but it is not commonly considered adaptable to steam roads in general, because it would be exposed to severe weather conditions mixed equipment, high speed impact, parts dragging on trains, and rougher usage generally than it has been subjected to in existing installations.

A refinement of the mechanical trip idea which has been used and reported to be successful on a number of limited stretches of steam railroads consists essentially of a fixed third rail ramp at each signal location, and a shoe carried by the train. In passing over the ramp the shoe is lifted and operates a brake valve, unless it receives current at the same time from the ramp. But if current is received it acts through a magnetic device to lock out the brake application valve. The ramp is energized by the roadside signal circuits when the signal indicates "proceed" but deenergized when the signal is set for "stop" or "caution". Various control schemes are on the market which have these broad features in common, but differ considerably in construction. In at least one case, provision has been made for giving several distinctive indications by vary-

ing the polarity and characteristics of the current supplied to the ramp.

The most fundamental weakness of this type of control, in common with all intermittent indication systems, is that failure to produce any indication necessarily acts as a safety, and not a danger signal. If the absence of an indication were made a danger signal, the trains would receive continuous danger signals from one ramp to the next whether the track ahead was clear or occupied. The train must be permitted to proceed in the absence of any indication between ramps; and if, owing to misadjustment or any other cause, the ramp fails to function, the train can continue past it, regardless of conditions in the block ahead. Nothing happens on the train to indicate that it has passed out of the block to which the last preceding ramp admitted it. The electric circuits in detail can be made conformable to the "closed circuit" rule previously discussed; but the system as a whole cannot operate on the closed circuit principle in its broadest sense, which requires every proceed signal to be given by affirmative action, and every failure of affirmative action to produce a stop signal. Intermittent track circuits in roadside signal practise are a somewhat parallel case. No ingenuity in their arrangement can make them indicate the presence of a train that has somehow got by them and stopped on the dead section between track circuits. In modern systems they have been superseded by continuous track circuits from end to end of the block.

The ramp type of control requires the establishment of special clearance lines, reserving some portion of the roadway cross section exclusively for the ramps and shoes. It seems hardly possible that it can be wholly free from trouble due to snow, sleet, and obstructions in the path of the shoe. On the other hand it is simple, and has behind it the record of more actual use than any other system, except the plain mechanical trip first mentioned. It can undoubtedly be made to give a valuable measure of protection if not the almost absolute protection (within their own scope) that is demanded of roadside signals.

An ingenious departure from the ramp type of control is a stationary flexible metallic brush beside the track, designed to make contact with a fixed shoe on the train. The brush is connected to the rail through a relay contact which is held open to indicate safety. The brake valve is held closed by a locally energized circuit on the locomotive, and released by short circuiting of this circuit in passing over the brush, unless the rail connection to the latter is held open in the relay. Unfortunately this scheme flagrantly violates the "closed circuit" principle in its most essential link, the shunt circuit through the shoe and brush to the rail.

In the permanent magnet induction type of control, large permanent magnets laid between the rails and below the rail level take the place of ramps. An iron

core on the locomotive surrounded by a coil takes the place of the contact shoe. Stationary coils are arranged in the region of the magnet poles. When the track is clear they are energized from the roadside signal system and serve substantially to neutralize the field of the permanent magnet. The magnet then has no effect on the train. But when the track is occupied, the stationary coils are dead, and as the train passes over the magnet it induces a momentary current impulse in the coil on the locomotive, which is located to pass over the magnet with a safe clearance. This impulse (acting through a relay) is utilized to cause a brake application.

Aside from the inherent limitations of all intermittent systems three questions suggest themselves, the permanence of the magnets, the degree of accuracy in neutralizing the magnet field, and the effect of passage over the magnet at low speed. The first question can be dismissed when we consider the permanence of magnets in voltmeters and ammeters—not merely approximate constancy such as is required in the track magnets but almost invariable strength over periods of many years. The answer to the second question is not so clear. The balance between the neutralizing coils and the magnet could never be exact; and if the supply voltage varies as much as is often the case in signal systems, it would be at times extremely rough. The locomotive coil, then, must distinguish not between a magnetic field and no field, but between a field of the normal strength and a reduced field of, for example, one third normal strength. If the apparatus is adjusted not to respond to the reduced field, it would seem that its factor of safety in responding to the normal field would be rather small, judged by signal standards; the more so when it is recalled that the apparatus must take care of a wide variation of speed as well, and some slight variation of air gaps.

Regarding the action of the magnet at low speeds, there will presumably be some minimum, such as four or five miles per hour required to produce an indication. So far as direct danger from collision goes, five miles an hour is equivalent to a stop. But there is a possibility that a train may enter a block at low speed for other reasons than a signal stop. Precautions should be taken to insure that the engineer will not then construe the failure to receive a stop indication as a sign that the track is clear. If he should so construe it, he could accelerate to a dangerous speed within the block.

The permanent magnet system has the marked advantage that it requires no modification of existing roadway and equipment clearance lines; and the further marked advantage that it has no contact parts and therefore no question of insuring contact in unfavorable weather conditions.

A very simple and ingenious modification of the permanent magnet scheme has a laminated iron core in place of the permanent magnet, with a corresponding core and coil on the locomotive. A winding on the

track core is short-circuited through a signal relay when the track is clear, and open when the track is occupied. The locomotive coil is continuously energized by a battery. When the track coil is short circuited it serves to choke back any magnetic impulse in its core (like a short-circuited transformer winding). Under this condition passage over the track element produces no considerable change in the locomotive circuit. But when the track coil is open, the magnetic surge in the track element as the energized locomotive element passes over it induces in the latter an inductive kick which results in a brake application. The advantages and disadvantages of this scheme are identical in many respects with the advantages and disadvantages of the permanent magnet arrangement. It would seem to have some advantage over the latter in respect to simplicity and perhaps a material advantage in the fact that its neutralizing circuit is entirely independent of variations in the voltage of the roadside signal system.

An entirely different system of control is the so-called "continuous induction" system. In this case the indicating energy for the locomotive is supplied directly to the rails of the track circuit in the form of alternating current, and collected inductively on the locomotive either by a coil located ahead of the leading wheels and surrounding a portion of the alternating field produced by the rails themselves, or by a small transformer surrounding the leading axle which acts as a single turn primary for the transformer. Detecting apparatus energized by the current induced in the locomotive circuit controls the application of the brakes or the indications of cab signals. When the track ahead is clear, the detecting apparatus is continuously energized and maintains the proceed indication on the locomotive. But when the track is occupied, or when the indicating current supply fails for any other reason, the locomotive apparatus reverts to its deenergized condition and a brake application results. The detecting circuit and apparatus on the train correspond exactly to the track circuit relay in roadside signal systems.

A train in a block automatically maintains a stop indication behind it in the same block by short circuiting the track circuit. But in order to stop a following train before it enters the block, it is necessary to carry the stop indication back to the next section in the rear. Several circuit arrangements which accomplish this are available, but none which utilizes the existing track circuits where roadside signals are installed without some additions. If desired, it is possible to give several distinctive indications on the train by varying the characteristics of current supplied to the track, or by superposing currents of different characteristics. The electrical efficiency of power transmission from the point of supply to the train is exceedingly low. The total energy input is the power consumed in a short-circuited rail circuit which may be several thousand feet long, while the energy collected

the signal indications. Two alternatives, then, are open. Either the signal No. 4 must be made a second stop signal with a caution indication at the preceding signal No. 5, as shown in Fig. 3, or the automatic action at the signal No. 4 must be made dependent on the action taken by the engineer at the same point or beyond.

In the former case it is evident that the minimum headway for full-speed signal indications is increased from two blocks to three, and the potential traffic capacity of the track is correspondingly reduced. But it should be noted that the traffic capacity of this particular section may still exceed the limit established for the whole operating division by conditions other than headway on the main line. It may easily happen in some cases that the traffic restriction here referred to would not in practice reduce the number of trains which can be operated over the whole division. In this connection it is interesting to note that extremely heavy traffic was operated for years in the New York subway system under exactly the conditions described; and when the growth of traffic demanded increased capacity, the need was met by improved air brakes which reduced the braking distance, and by special signaling in the station approaches (which were

FIG. 2

the actual limitation on track capacity) to permit closing in of trains at reduced speed.

The second alternative mentioned was to cause a conditional instead of an unconditional brake application at the caution signal. Several methods of accomplishing this conditional control are proposed.

The simplest of these is a cut-out under the engineer's control or the joint control of the engineer and fireman. If the caution signal is acknowledged while passing it, by operating the cut-out, the train proceeds under manual control without interference. In other words instead of actually enforcing train operation in conformity to the signal indications, acknowledgment of caution signals is enforced, on the theory that an engineer sufficiently attentive to acknowledge the signals can be depended on to take the necessary action when required. But acknowledgment of a signal does not absolutely assure that it has been correctly interpreted. It would be possible for the engineer to operate his cut-out at every signal, regardless of its indication.

Another proposal involves a modification of the present operating rules. A definite speed limit is established for the caution block, and the engineer on passing a caution signal is required to reduce his speed immediately to the prescribed limits. If he makes a sufficient brake application for this purpose promptly at the cau-

tion signal, the automatic control apparatus does not interfere; but if he fails, the automatic control does it for him. In one system a second indication for full stop is provided at a sufficient distance from the stop signal to bring the train to rest from the speed prescribed for the caution block. This plan restricts train movement in so far as it enforces a speed reduction earlier than safety and the present operating rules require. In the case of long blocks this may become a substantial restriction. The scheme appears to be safe in principle.

Still another method is to hold the automatic brake application in suspense from the time the caution indication is received to the time the brakes must be applied to stop at the stop signal. The actual time of application varies with the speed of the train, just as it does in manual control. In other words, the point of brake application varies in accordance with the curve of braking distances for various speeds. For convenience we can designate this as the "braking curve" type of speed control. Several methods of determining the point of brake application have been worked out. In one of these the caution indication is repeated at diminishing intervals as the stop signal is approached, the distance between each two successive indications corresponding to a certain time interval when the train is moving at the greatest speed permissible at that location. Two indications received in less than the established time interval show that the speed exceeds the limit set in the spacing of the indication points, and cause an automatic brake application. This principle has been applied for establishing speed limits at certain points in the New York subway system. The successive indications in that case took the form of roadside signals located at short intervals, with an automatic stop arm associated with each signal. The time intervals were measured by the relays which controlled the signals.

Another method involves a cam driven from an axle of the train. As the train proceeds through the caution block the cam establishes diminishing speed limits, and a speed-indicating element causes the brake application whenever the actual speed exceeds the limit established by the cam.

Still another method comprises a flywheel retarded periodically from a speed proportional to that of the train. The angular movement of the flywheel during retardation is a measure of the distance required to arrest the train; and when the distance remaining to the stop signal has been reduced to the indicated braking distance, the brakes are automatically applied.

All speed controls of the "braking curve" type require the automatic caution indication to be effective at a uniform distance from all stop signals. This type in common with the type based on limited speed in the caution block restricts train movement in one respect. In manual operation it often happens that an engineer after passing a caution signal finds the succeeding

signal at caution instead of stop when it comes in view. The train which caused the original stop and caution signals has passed on to the second block ahead. Under these circumstances he accelerates again, and prepares to stop at the second signal. But in the case of any automatic cycle initiated by an intermittent indication from the track, the cycle would continue automatically to completion. The train would stop, and then proceed in accordance with the signal received at the next indicating point.

In connection with Fig. 2 it was shown that the headway of trains under manual control can be substantially reduced by subdividing the signal spacing determined by the braking distance of the fastest trains. The same thing applies with equal force to automatic con-

FIG. 3

trol; and in fact involves less added complication than in the case of roadway signals; for the semaphores themselves, with their supporting masts or bridges are a major item in the latter case. Multiplication of signals would soon become prohibitive. In the case of automatic control on the other hand the increased equipment consists chiefly in the added circuits, with their associated relays, etc. Furthermore the number of speed indications which can be intelligibly given by semaphores is limited, while any reasonable number of indications can be provided for in the locomotive cab. Fig. 4 illustrates a case in which the maximum braking distance is subdivided into three indicating sections. In each section the speed is limited to a value which permits of stopping the train between the exit of that

FIG. 4

section and the entrance to the occupied block. At the entrance to each section an unconditional stop is assumed for any train running at a higher speed than the limit effective in that section. A warning (corresponding to a caution signal) is therefore necessary at the entrance to the preceding section. The warning signals are represented in Fig. 4 by circles inclosing the speed to be indicated. They may be roadside signals or signals displayed in the cab. The example illustrated gives a minimum headway of $1\frac{2}{3}$ blocks for operation under full-speed signals, as compared with two blocks for manual control in Fig. 1, and three blocks for unconditional stop with one block overlap in Fig. 3, with shorter headway for lower speeds. Theoretically, the headway could be further reduced

by one-third block by combining the subdivided blocks with any of the plans already discussed for qualified control initiated at the caution signal.

To illustrate the relation of the various control cycles here discussed to headway and traffic capacity, the headway attainable under certain assumed conditions has been tabulated in Fig. 5. Headway is expressed in seconds rather than feet in order to show more directly the bearing on the potential traffic capacity of the track, in trains past a given point per hour. The conditions assumed are:

Time counted from the head of one train to the head of the following train.

Train length, 1000 ft.

Maximum speed 75 mi. per hr.

Train speeds 40, 60 and 75 mi. per hr.

Retardation 1.5 mi. per hr. per second.

No allowance for time consumed in operation of semaphore signals.

FIG. 5

The following train is assumed to approach each signal just as it assumes the permissive indication for the speed at which the train is running. The permissive indication for manual operation is considered to be the "proceed" signal at all speeds; for although it is permissible to pass the caution signal at speed, it is not permissible to maintain the speed throughout the block, unless the following signal is visible before the time comes to apply the brakes; and the range of visibility varies with location and weather. In most cases of manual operation at speeds below the maximum, a smaller headway than the table shows can be maintained by running under caution signals. The same is true of "condition" control by continuous induction without reservation as to visibility.

Line A refers to manual operation with signals spaced at the maximum braking distance. The same headway is required for any of the "conditional stop" arrangements with the same signal spacing and the stop indi-

cation at the caution signal. *B*, *C*, *D*, and *E* are for one section overlap with an unconditional stop effective at the rear stop signal and the necessary caution signals back of the stop. They show respectively one, two three and four automatic stop sections in the length of the maximum braking distance. With the subdivided blocks, progressive speed limits are provided. Line *C* with the braking distance subdivided in two sections gives the same headway at the higher speeds as manual control without overlap. The smaller subdivisions permit reduced headway. Lines *B*, *C*, *D* and *E* respectively require two, three four and five distinctive control and signal indications.

CONCLUSIONS

The substance of the matter seems to be that practical means are available for any kind of control likely to be required in automatic territory, though only a few of the arrangements described have been worked out in actual railroad service on any considerable scale. From a safety standpoint the arrangement that most clearly conforms to sound signal practise is perhaps the unconditional stop with an overlap of one control section, whether the control section is the total braking distance as at *B* in Fig. 5, or a subdivision of the braking distance as at *C*, *D* and *E*. This arrangement lends itself readily to any required concentration of traffic but it requires more track circuit and control circuit apparatus for equal headway than the conditional stop arrangements installed as shown at *A*.

Comparatively few railroads at the present time have signals spaced for the minimum safe headway, and it is not probable that the maximum possible track capacity will be required on any considerable mileage of the roads equipped. It would seem a natural development to retain the present signal spacing on the major portions of the roads, either with unconditional stops and one block overlap, or with conditional stops effective at the caution signal; and to provide the needed capacity at points of special congestion by relocation of signals when they are not now spaced at the minimum permissible distance, or by subdivision of the blocks where signals are already so spaced. Where extensive changes of existing signals are required, it would be worth while to consider whether the same result can be more economically obtained with cab signals.

With automatic control in force, it seems likely that the future trend of signal development will be toward cab signals rather than roadside signals; first because they are inherently capable of giving greater protection, and secondly because they involve less apparatus over and above that required in any case for the automatic control. If this is true, the railroads may find it desirable in making their present automatic control installations to give some consideration to possible future requirements for cab signals.

Discussion

Frank J. Sprague: I wish to refer to the tests which have been going on on the New York Central Railroad since the 20th day of February, a year ago, on so-called automatic train control. What is the object sought in train control? Simply to marry together the traffic conditions which exist on a railroad, no matter how indicated or governed, whether by manual signals or by automatic signals, with the braking system of a train in such manner as to insure the complete protection of that train movement, the reinforcement of any wayside indications, the amplification of those indications in the cab of the engine, or their replacement, without encroaching upon the prerogatives of the engineer when properly exercised, and without limiting the capacity of the railroad operation.

That means not an "automatic stop" in its simple form, because it has little value on a modern railroad system. It has to be placed either too far back, so as not to interfere with traffic, or too far forward, so that it will not itself protect traffic. Nor must there be an automatic system, in the sense that trains are to be run automatically. It must be an auxiliary system, something which leaves to the engineer that which properly belongs to him, the handling of his train according to the great varieties of conditions that exist in operation, all the while protecting him, but in no case unnecessarily interfering with him.

Therefore the system should be called an "auxiliary" and not an automatic, system of train control, one where operation is automatically initiated, but under the control, so far as proper, of the engineer himself.

There have been several systems mentioned. They may be divided into two broad classes. First, intermittent; and, in this class, we have the rail-contact ramp devices, also the inductive method of initiating impulses on the locomotive, either by induced electromotive forces in the control circuits, or by direct magnetic action; and then there is on the other hand the so-called continuous system, illustrated by wireless or by the picking up of induction from the rails themselves, as well as other methods unnecessary to mention at the present moment.

Train control has had a hard road to hoe, as those who are interested in it know. There have been over a thousand proposals before the United States Government, and one of the leading signal engineers of the country said there had been over four thousand proposals before the railroads.

Opponents of train control have largely ignored the possibilities of a properly developed system, the making less necessary, or insuring a simplification or reduction in the use of wayside signals,—leaving out for the moment the making possible a two-way operation of every track of a multiple-track railroad, with cab signals operated in either direction of traffic. Those are perhaps the two larger results to be obtained, not merely the humanitarian one.

The United States Government, however, has looked more particularly to the matter of safety, and the Interstate Commerce Commission recently has ordered 49 railroads in this country, to each equip, within two years, a complete engine division in certain specified localities. Their order covers only a very small proportion of the mileage of the large railroads, but this work has got to go ahead now and in the course of two years there will be a goodly number of systems in operation.

Some will bring, no doubt, disappointing results to the railroads, and with the possibility of inducing dangers which they were intended to eliminate. Some of these cannot be avoided, but we hope, as to others, the results will be satisfactory. Up to the present the few systems in use in this country are of the so-called rail-impact type.

This has one fundamental and serious objection, which I will specify and illustrate by reference to three exhibits laid before the Government at Washington. It is based upon the idea that at every block over which a train passes there must be

operated a shoe whose object it is to apply the brakes, but such application is to be prevented when the block is clear, by the supply of electric current to that particular ramp rail.

You would be surprised to see and know perhaps how few times automatic operation should be called into play. I will illustrate very briefly by facts taken from the official records:

On three railroads, which I will designate as A, B and C, we have the ratio of needed brake applications to the number of blocks passed over as follows: A, 1 in 414; B, 1 in 1491; and C, 1 in 37. If you have an apparatus which is operated every time you go past a block, it is operated a hundred or more times, as frequently as called upon by adverse traffic conditions.

The great difference between that kind of a system and the induction system, no matter of which type, is that the apparatus operates only when it is required, and not the many times not necessary. In other words, it is required probably on an average of perhaps once in one hundred blocks, based upon the average density of train service in the United States.

The Joint Committee of the American Railroad Association and the Interstate Commerce Commission about a year and a half ago started to have certain sundry tests made in this country, and among others there was one initiated by my own company, carried on on the New York Central Railroad on the No. 2 track, the same track used by the 20th Century. It started a year ago and for the past two months it has been under closed sealed tests. Some idea of the intensity of that test may be indicated when I state that the number of brake tests have been from thirty to five hundred as many as occurred on the roads above mentioned, and the brake applications made during the two months just closed is what would have occurred, in average density of operation, on a train five times encircling the globe at the Equator.

Mr. Blake's paper omits reference to what has been done over a very considerable period, and those facts should ultimately be placed upon the record.

Azel Ames: It is to be regretted that Mr. Blake uses the word "engineer" throughout to denote the locomotive operator rather than the official designation of "engineman". It is suggested that the terms "main line" and "terminal" territory would be more precise than the terms "block signaling" and "interlocking" territory used in paragraph 9 for the reason that nowadays automatic blocking is carried through all main line interlockings and automatic train control would naturally be carried through them when installed on any given section of main line. In terminals where slower speeds are called for, automatic train control would of course be less necessary and vastly complicated.

The author points out the superiority from the safety standpoint of "continuous" as compared with "intermittent" control and also the greater facility which "continuous" control offers for the installation of cab signals. On the other side it may be said that with existing types of continuous control considerable inconvenience is likely to be encountered especially with work or construction trains due to the impracticability of pushing cars, snow plows, or other types of equipment ahead of the engine. It is also well to remember that while the principal protective feature of "continuous" control lies in causing a stop application in the event of a switch being opened or a train pulling out of a siding after the approaching train has entered the block, we cannot be sure that these untoward events will always happen when the approaching train is full braking distance, or even half that distance from the point of obstruction.

In noting that all speed controls of the "braking curve type" require the automatic control indication to be effective at a uniform distance from all stop signals, the author is undoubtedly assuming level track conditions, as the distance would vary with the grade of the approach to the stop signal.

Mr. Blake's paper refers principally to the signaling and train

spacing features of the automatic train control problem and to the various means employed to produce an impulse or effect in the engine cab as the result of certain conditions upon the roadway. It would have been very interesting if he had touched upon that much neglected phase of the problem, namely, that of braking. For years discussions of automatic train control have seemed to assume that if a magnetically controlled valve somewhere in the braking system could be opened to permit a reduction of air pressure when it was desired to stop a train, the problem had been solved. Our present highly efficient automatic brake systems have been designed entirely for manual operation and many of their characteristics might be quite different if they had been designed for automatic control. Perhaps the most serious phases of the automatic train control problem after all are the great variety in the braking power of trains, especially freight trains, the large time elements involved in application and release in long trains, the necessity for release to accomplish a second application on long down grades and the enormous cost of changes in the existing equipment.

Most of these are matters for mechanical rather than electrical solution, but it is very desirable that the electrical engineer studying automatic train control should realize that it is the brake that must stop the train and that his electrical apparatus and circuits must be designed with the characteristics of the braking system always before him.

T. S. Stevens: Quoting from page 27: "The primary function of automatic train control is, of course, to stop the train before it enters upon unsafe territory."

This has been true with reference to older developments, but the tendency now seems to be to stop the train only when the engineman fails to properly reduce speed.

Page 32: "Furthermore the number of speed indications which can be intelligibly given by semaphore is limited while any reasonable number of indications can be provided for in the cab."

This sentence seems to be definitely at discord with the actual conditions. While I do not agree with the signaling methods used on a considerable mileage of the railroads, largely because of the lack of necessity for a large number of speed indications, the facts are that on very many railroads, where three-arm signals are used, quite a number of varied speed indications can be provided intelligibly which are absolutely impossible to provide in the locomotive cab. So far, if the stop indication is included, the manufacturers have been able to provide four speed indications: high, medium, slow and stop. As a point of fact the majority combine the slow and stop indications so that only three are provided.

M. E. Pipkin: Mr. Blake's paper gives the impression that the author considers continuity of indications on the engine a highly desirable feature in train control, if not an absolute essential. In this connection, it is interesting to compare the situation with that which obtains in the present roadside signal systems. In the roadside systems and in all of the automatic systems described by the author the track is divided into definite blocks and the control required is with definite relation to these blocks. Specifically the requirement is that the train stop at a definite point, namely at the entrance to an occupied block. Furthermore, the indication that a stop is required becomes effective in all cases at a definite location namely, the beginning of one or another block section. In the case of roadside signals, the necessary warning is given at the logical point, namely the point where it becomes effective. In other words the fixed roadside signal is essentially an intermittent indication confined to a definite location for each block, precisely as is true in the case of the intermittent control systems described. In both cases the control of the indication including track circuits and control circuits from the opposing train back to the actual

indicating point is properly continuous, but the indication itself is intermittent.

E. J. Blake: Mr. Sprague's discussion emphasizes effectively two points mentioned in the paper; the necessity for avoiding anything that will supersede the engineman when he functions right, and the insufficiency of the plain automatic stop when traffic capacity has to be maintained. I agree with him that we can expect, and should provide for, simplification of roadside signalling and increased facility of train operation, as well as increased safety with the adoption of automatic train control. That has been the history of roadside signalling. It was introduced as a safety measure, but has become recognized equally as a measure for facilitating train movement. The particular case cited by Mr. Sprague is not altogether peculiar to automatic control; two way operation of multiple tracks has been provided for in a number of cases by the use of roadside signals.

Mr. Sprague does not make wholly clear just what is meant by the "ratio of needed brake applications to the number of blocks passed over." If he means that the engineman disregarded stop indications so that automatic control should have come into play in one block out of every 414, or 1491, or 37, the last figure seems surprisingly small. In any case we can agree that actual operations of the automatic control necessitated by failure of the engineman ought to be exceedingly infrequent. But it does not seem especially important what the control apparatus does the ninety nine times it is not required (assuming that it does not interfere with the operation of the train). The essential thing is certainty of operation in the hundredth case when it is needed. We have a somewhat similar case in roadside signalling. The signals ordinarily operate at the passage of every train, irrespective of the presence of a following train for which the signal indication is required. It is to be hoped that the results of the New York Central tests to which Mr. Sprague refers will be published in due time.

Major Ames's comments on the terminology of the paper are well founded. "Engineman" "main line" and "terminal" territory are more precise than the terms used in the paper. I cannot agree with him that the principal advantage of continuous control from a safety standpoint is response to danger arising after the train has entered the block. It has this advantage, but as Major Ames points out, nothing can protect a train against a danger that arises too near it to permit of stopping. The fundamental claim of the continuous systems to superior safety as I see it is the fact that they can be arranged to respond to every cessation of energy as a danger indication, just as is true of roadside signal apparatus. Every intermittent system necessarily responds to some action at the indicating point so that absence or failure of the action is, in effect, a false proceed indication. Protection for equipment pushed ahead of the locomotive is a real difficulty; but in the case of work trains at least it would seem reasonable to operate with the automatic control cut out, just as they are frequently operated under "work orders" without regard to fixed signals or the direction of traffic.

The reference to uniform location of control indications

for "braking curve" control should have been qualified as suggested with regard to grades.

Major Ames points out that proper air brake control after suitable traffic indications have been received is a serious problem in itself. This is true in some degree for all control cycles, and particularly, for the cycles based on slowing down to a prescribed speed at caution signals; for in this case the automatic device must check the sufficiency of the brake application even when it is initiated by the engineman. But it should be borne in mind that the automatic control is intended to stop the train only as a last resort in the infrequent cases where the engineman fails to do so. Under the circumstances, rough and even dangerous handling of the brakes might be tolerated in preference to continuing to run unchecked into the obstruction.

The first passage quoted by Mr. Stevens, when read with the sentence which follows it seems to say substantially what Mr. Stevens says in his comment. But the second passage (page 32) may be unintentionally misleading. It is true that the number of simple and desirable aspects available with semaphore signals is limited because the semaphore (and its light indications at night) must be read at long range and under unfavorable conditions; and it is true that no such limitation exists for cab signals. As an extreme illustration the engineman is able to distinguish clearly seven hundred and twenty distinct minutes in twelve hours on the face of his watch. But it is not true that unlimited indications can be transmitted from the roadway to the train without very great complications. Practical developments to date have been confined to the simplest available circuits giving three or at most four indications on the train as stated by Mr. Stevens. It is likely that these indications will suffice for a great majority of future installations; but it is far from impossible to give a much larger number if the need should justify the cost.

Mr. Pipkin cites an interesting parallel between train operation under roadside signals and under automatic control, and concludes that intermittent indications on the train are a logical result of the subdivision of the track into blocks at definite points. The analogy is not wholly valid, because the roadside signals are commonly visible through a considerable part, and often through the whole of the block. In the latter case the indications received on the trains are strictly continuous, notwithstanding the intermittent location of the signals themselves. Furthermore the point at which action is required to bring the train to a stop at the entrance to a block is not definite but varies with the speed of the train. An engineman approaching a stop signal often sees the signal change to caution before he is obliged to set the brakes; or sees the signal change before the train has come to rest, releases his brakes and proceeds. In either case he is taking advantage of a continuous indication, extending back to the visible range of the signal. It is the universal custom to locate roadside signals with a view to getting the longest practicable range of visibility—that is to give continuous indications to the engineman as nearly as possible; and even where the range is shortest the indication is by no means comparable with an instantaneous impulse during passage by a definite point.

Discussion of Application and Economics of Automatic Railway Substations

BY L. D. BALE

Associate, A. I. E. E.
Cleveland Railway Co., Cleveland, O.

Review of the Subject.—The automatic substation is defined, and its history is traced from the first station placed in service in 1914 to the present time. The number of automatically controlled railway stations up to the beginning of 1922 is given as 142 equipments totaling 86,000 kw. Outside the city of Cleveland, two-unit stations have been installed in but four instances, although a number of these stations are now under construction. With manually operated stations, especially in interurban work, the location of stations is determined by local conditions, availability of labor, etc. rather than by load conditions. But with the advent of the automatic substation it is possible to locate stations more nearly at the proper points to take care of the system loads giving improved voltage conditions with a minimum of feeder copper. Accessory advantages, in addition to the labor saving item, include a reduction in running light losses, a reduction in distribution losses, lower cost of substation and, in some cases, an actual retirement of existing feeder copper. An example is cited of a double track line 80 miles long with figures from a report which shows a net annual return on the investment, including 6 per cent interest, of 34.9 per cent. The labor saving is based on two twelve-hour shifts, and it is further calculated that with three eight-hour shifts the annual saving would be increased by an appreciable figure. The Des Moines City Railway was the first system to install a group of automatic substations for city service, while the Cleveland Railway Company is given credit

for installing the first two-unit automatic substation for metropolitan railway service. Reasons are advanced for using two-unit stations in Cleveland in contrast to the general practise of employing single-unit stations in interurban work. Emphasis is laid on the necessity for absolutely uninterrupted service in a large city system, even under such emergencies as either an interruption of the a-c. power supply, or short circuit due to breaking of the trolley wire. A further comparison between the operation of manual and automatically controlled substations is taken from one of the surveys made in Cleveland. The tabulation indicates a net annual saving of \$13,900 per year for the automatic over the existing stations.

As to the reliability of automatic control equipments, conclusion is reached that an operator is very unlikely to anticipate trouble, whereas with automatic control the protective equipment operates so successfully that various interruptions are a rare occurrence. There is also the possibility of an operator making an error in judgment, thereby causing trouble which might not otherwise occur. A further consideration which should not be overlooked is the possibility of loss of operators due to strikes or other causes. An outline of the equipment used in the Cleveland stations is given with special reference to outgoing feeders and the proposed method of eliminating current-limiting resistance. Description is also given of the remote control equipment now being manufactured, which will enable the several automatic stations to be supervised from a central point by a dispatcher.

PERHAPS for the benefit of some of those who have not had the opportunity to follow this development a definition of an automatic substation will not be out of order. Messrs. Allen and Taylor define the automatic substation as a substation in which the functions of starting and connecting machines to the line whenever there is a demand for power and finally shutting down, after the demand for power has been satisfied, are all performed in their proper sequence without the assistance of an operator, either in it or at adjacent stations.

Further, it might be added that to make this scheme possible, there must necessarily be arrangements made for taking care of the equipment in such a substation, and protecting service under all of the operating conditions which railway power equipment is subjected to.

The first successful installation of an automatic railway substation, as far as I am aware at least, is the installation of a 300 kw. 600 volts, 25 cycles, 3-phase, synchronous converter on the Elgin & Belvedere Electric Railway, an interurban road. The equipment in this substation was rearranged for automatic control and placed in service December, 1914.

The idea of automatic control for this station, as I understand, originated with an engineer in the employ of one of the large electrical manufacturing companies,

who upon presenting the idea to his company was informed that it was impractical. He, however, thinking otherwise, broached the subject to Mr. B. J. Arnold, who, I believe, was interested in the Elgin & Belvedere Railway Company. In any event, after securing a miscellaneous assortment of relays, contactors, and such other equipment that was applicable to this control system, and was at that time more or less standard in steel mill control work, the station referred to was put into successful operation.

Needless to say, after the practicability of the idea had been demonstrated, the manufacturing companies adopted it. It is, therefore, noteworthy that the history of the automatic substation does not extend over an appreciable length of time. But, in this period there has been a wide adaption of the scheme throughout this country.

A summary of automatically controlled synchronous converters and motor-generator sets in railway service up to this time a year ago, discloses the fact that there are some 80,750 kw. of converters and some 5200 kw. of motor-generator sets in railway service automatically controlled. The capacity is distributed over 129 installations and involves a total of 142 equipments. The majority of these being stations containing a unit of 300 to 500 kw., although there are some 1000-kw. converters involved. Of the 129 installations there are but four cases, except Cleveland, where two units were used in one station. There are, of course, numerous

Presented before the Cleveland Section, A. I. E. E., April 18th, 1922, also at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 14-17, 1923.

recent installations not included in this list which have been placed in operation since the tabulation was made. Today, I understand, there are about half again as many orders for equipments of this type upon the books of the two manufacturing concerns building this equipment.

There is as far as this discussion is concerned, three general types of electric railways. The first of these groups is the interurban system, with which as far as we are concerned may be included small suburban systems. In this type of service there is found by far the greatest number of installations of the automatic substation. The idea originated on an interurban system, as was noted, and it is in this class of service that the greatest savings are possible when compared with the manually operated plant. Further, the more infrequent the service the greater will be the proportional saving beyond the item of labor saved. A brief discussion of some of the principal items is as follows:

With manually operated plants in interurban work, it is too often the case that the location of the plants instead of being decided by the load conditions, is of necessity influenced by having to place the station either in or near a center of inhabitants wherein the station operator and his family may live, for without at least some of the conveniences of modern civilization, the railway companies are presented with the inability to secure competent help or are compelled to pay exorbitant wages to hold a sufficient number of competent men to operate the stations.

The necessity of having two or in some cases three shifts of skilled attendants for each station also influences the number and size of such stations, that is, the number of stations provided are held at a minimum, which in turn is reflected in the amount of feed copper necessary to connect the station with the load. Therefore, it is readily seen that if the human element could be eliminated from the operation of a substation, that the station could be located with respect to load only. It is desirable to have as many stations feeding a line as are economically possible, for by this method the feed copper may be held to a minimum, the operating potential of the line may be maintained, and a greater guarantee of service is gained by reason of the numerous points of supply. The approach to this ideal has been made possible by the advent of the automatic substation development. There are other items of savings referred to previously made possible by the use of this type of station on interurban lines. Principal among these items, is the elimination of light load running losses. These losses on an average interurban line may amount to considerably over a period of twenty-four hours where the headway between cars is infrequent. With automatic equipment the station will shut down after the car has run beyond the territory served by the station and the station will again start as the next car comes into the territory. On single-track lines with cars spaced an hour apart, and possibly meeting somewhere in the vicinity of the station, there are instances

where the substation is required to run for only fifteen or twenty minutes out of an hour. This frequent starting and stopping of the equipment is not done if the station is manually operated, consequently with the automatic substation, the average load carried on the equipment may approach more nearly the point of highest operating efficiency. Distribution losses are reduced on account of the possibility of utilizing more stations and locating them where required without having to consider increased labor in operating costs. The cost of the substation building may be materially reduced, for it is unnecessary to provide the usual clearances around equipment, likewise, the apparatus may be arranged with regard to a minimum size of building, rather than to ease of operating as is necessary in arranging for manual control, also facilities for the comforts of the operator are eliminated.

The advent of the automatic substation for interurban work has resulted in several instances in a complete rearrangement of the power facilities of some of these lines, while on others, automatically equipped stations have been installed between existing manual stations, eliminating the necessity of installing additional feeder copper to care for increase in load, in several instances allowing copper to be removed, at the same time increasing the average trolley voltage and at no increased cost of operation. An instance where the power facilities of an installation could be completely rearranged at a considerable saving in operating cost is illustrated by the following summary of a report made on an eastern property. This property operates a double track line approximately eighty miles long.¹ The schedule is essentially one car each way every forty minutes. Local cars are operated at schedule speed of 23 mi. per hr., and limited trains at 30 mi. per hr. The power is supplied to the trolley at 600 volts d-c. from eight manually operated substations spaced approximately ten miles apart. There is a .0000 trolley wire over each track and in addition a 500,000 cm. feeder running the entire length of the line.

It was proposed to retain five of the present substation locations. Three of the present substations are to be moved to new locations and there will be four additional substations made up of equipment now used as spare apparatus in other stations. This will make a total of seven new buildings and eleven automatic control equipments to be supplied, together with high-tension switching for each station.

The balance sheet for this proposed installation of automatic control on this interurban is as follows:

<i>Investment Required</i>	
Seven new buildings.....	\$20,000
Auto. control, etc. high-tension switching..	125,975
Installing of switching equip. and reinstal- lation of rotaries and transformers....	16,300
Total.....	\$162,275

1. From report by Mr. C. A. Butcher, Westinghouse Electric & Mfg. Company.

Rearrangement of feeder system.....	\$6,030
Removal of 66.58 miles of 500,000 cm. cable at \$50.....	3,330
Extension of transmission system.....	4,350
Gross Investment.....	\$175,985

Credits

85-1/10 miles of 500,000 cm. cable at 18c. per pound.....	\$123,000
Salvage, other materials.....	6,000

Total.....	\$129,000
Net Investment.....	\$46,985

Annual Savings

Operators' wages eliminated.....	\$22,330
Power saved.....	2,860
Other misc. substation savings.....	200

Total.....	\$25,390
------------	----------

Annual Charges

Inspectors' wages.....	\$4,725
Fixed charges, not including interest on investment.....	4,230

Total.....	\$8,955
Net Annual Saving.....	\$16,435

Return on investment including 6 per cent interest.....	34.9 per cent
---	---------------

Return on investment not including interest.....	28.9 per cent
--	---------------

Total investment would therefore be retired in approximately 3 1/2 years.

The labor saving shown in the table is based on two twelve-hour shifts of one man per each station. At the time this report was made an eight-hour day was in demand. This would increase the item of labor by a third and under this condition the net annual saving would be increased to \$23,878. By this new arrangement of power and distributing system the trolley voltage at the car would be increased by twenty volts. This would result in an increase in running speed and therefore a possible decrease in platform expense, that is, train crews.

You may now realize that the automatic substation has adapted itself ideally to the interurban field where the savings made possible by its application are most apparent. Until about 1918 the automatic equipment was limited almost entirely to the interurban field. This was due, I believe, to the greater cost of the control equipment compared with manual equipment of the same capacity which was thought apparently could not be justified unless savings made possible by its application were without question large, also the scheme was looked upon by quite a few as more or less of a makeshift for use only on the small suburbans.

To Des Moines, Iowa, a city of 126,000 inhabitants belongs the credit of advancing the application of this type of station one step from the purely interurban service. The Des Moines City Railway operates 91.27 miles of single track and 150 cars of all types including interurban, had in operation in 1921, eight or nine automatic substations of 500 kw. capacity each, in city and interurban work. These installations, as I recall, represent simply the use of the interurban type of

station to move city cars, and no new departures were made by reason of the different service.

The next step in progression was made in Cleveland. The Cleveland Railway Company has in operation today, three automatic installations which represent the first case on record of the adaptation of the automatically controlled substations to metropolitan service. These installations also enjoy the distinction of being the first two unit automatic substations of large capacities having been constructed. Each of these stations contains two 1500-kw., 60-cycle, converters. I might add that to date they are the only installations of their kind in existence.

While the application of automatic substation to the interurban system is now on more or less of a standard basis, variations being slight, and principally in kw. capacity, the question of applications on metropolitan systems does not lend itself to standardization nearly so readily. This fact must be realized when the great variety of conditions, principally brought about by operating practises, are considered on various large city systems.

When the problem of layout or rearranging of power generation and distribution facilities of a large system is considered, it will be found that there are numerous items which enter into and effect immensely the ultimate results, that do not appear in planning for the interurban system, and further the weight of these various problems regarding the whole, change, dependent upon what particular city one may be working in.

The various problems are closely co-related. Unfortunately the time available will not allow a full discussion of all the various phases, but, briefly, the results obtained in a survey depend primarily upon the importance of the station or stations to the balance of the system, that is, whether the station is located on the outskirts of the city, in which event it may be considered of relatively less importance than one located perhaps in a congested area serving possibly several important lines of transportation. The area or zone to be supplied by a given station, that is the current density, which also fixes the kw. capacity of the station, is in general determined by land value, building cost and restriction, reserve capacity, a-c. and d-c. feeders, investment necessary in building equipment and feeders, together with annual charges and losses. The paramount necessity, however, is that the system must be conducive of a high degree of reliability of service.

Still another factor referred to previously as "operating practise" has a direct bearing upon the question. It is this phase that tends to make it almost impossible to standardize or make comparisons of proper power facilities for metropolitan systems. By "operating practise" I refer particularly to the quality or type of service rendered by the operating company to the car riding public. An illustration will perhaps make this more clear. The principal source of trouble to the power department of a railway company comes from

the falling of a trolley wire, bad order car equipments, and overloads due to traffic delays, etc. When a trolley wire breaks and grounds, it is of course disconnected from the source of power at the station by automatic breakers, that is, if manual stations are used. On a great number of roads it is the practise to hold these grounded feeders or sections open until the wire has been picked up either by the car crews or the line emergency crews. The power plant is then notified and power is restored. By this procedure the amount of trolley wire annealed or destroyed is held at a minimum as is also the matter of maintenance on station equipment. The great disadvantage of this method, however, lies in the fact that important lines are tied up for indefinite lengths of time, schedules are disarranged which on heavy lines may require the remainder of the day to rectify, and most important of all, thousands of patrons of the line are delayed, in some instances seriously.

The progressive management is really trying to produce the best possible service, free from interruption, realizing that to have cars standing in the street without power, does not, to say the least, improve public relationship.

For example, the management of the railway in Cleveland is most insistent in its demands that power be supplied under all conditions. When a short circuit occurs upon a feeder section, instead of leaving the section out or dead, until the trouble has been cleared, every attempt is made to maintain the power supply upon the faulty section, for, with power the cars continue to move. To make this possible, it can readily be appreciated that the layout of the generating and distributing system will be considerably more extensive, more complicated and expensive, than on a property where power service is discontinued when trouble arises on the line.

The question of the size (kw. capacity) and the number of units to be installed within the automatic substation in metropolitan service is one which also is receiving much discussion at present. There is no question but that to increase the number of points of supply to a system will result in a better average operating voltage at the car, and with a reduction in the amount of feeder copper necessary, also by reducing the potential gradient of the rails do much to eliminate electrolysis. It would, therefore, appear that the ideal layout of automatic substations should consist of a series of small single-unit installations located at relatively short distances from each other and in a very simple, small inexpensive building. With low land values and building cost, and the absence of building restrictions, which are encountered generally in small cities, sparingly settled areas or suburban districts of larger cities, there seems to be no doubt but that a number of single-unit installations answer the requirements admirably. On the other hand, where the cost of

land and buildings is high and there are numerous restrictions to be complied with as is the case in Cleveland the multiple unit station works to the greatest economy, taking every item into consideration. On the metropolitan system where continuity of service is the one ruling factor, it is necessary (as was previously noted) to protect or make possible this continuous service by installing reserve capacity in equipment and distribution system. To exemplify this, take but one of the phases necessary for insurance to continuity of service, the a-c. power supply.

In small cities where underground construction of high-tension lines is not necessary, the cost of connecting the a-c. power supply to the numerous small single-unit stations is not much of a factor. On the other hand, in large cities, where underground construction is necessary, the cost of supplying all of the small stations with a-c. lines becomes an expensive matter. In this connection, the installation of duplicate a-c. feeders to a station of importance containing more than one unit is warranted, insuring as it does freedom from station "shut downs" arising from a-c. line failures. In the case of less important stations having but a single unit, this feature of safety to service is sacrificed, for the duplication of supply cable being in the case hardly permissible. Where the multiple-unit station proves the most efficient and economical type to install, the factor of service insurance is further increased by reason of the scheme of automatic sequence which is a part of this type of station.

On the average interurban system the load taken as a whole upon the system tends toward a flat characteristic, that is, each of the stations upon the system is subjected to numerous peaks during the period of operation of the line. These peaks occurring when there is a train within the territory supplied by any particular station and as noted previously as the train moves out of the territory, the station shuts down. On the large city system, the load is of an entirely different nature. There is a continuous load on the station which varies more or less gradually from the peak condition, morning and evening, to the base running schedule period. In the former case, that of the interurban, the power equipment is being worked to the highest possible over-all efficiency. In city service, however, the frequent starting and stopping of equipment is impossible, for with all stations upon the system arranged to feed into what results, by reason of emergency tie feeders, a general network of feeders, and with very low ohmic resistance (0.03 approximately) between stations, each and every machine in service will attempt to assume its portion of the system load. This tends to keep equipment in service when there is really no necessity for same. This would result detrimentally to the all-day station conversion efficiencies. There is, of course, a limit that can be established above which an increased average trolley potential will not reduce platform or

other expenses materially. Beyond this limit it is obviously unnecessary to have converter equipment operating at the resulting low-load factor.

The two-unit station has an advantage in this connection, in that the two units will operate to capacity during the peaks, while the remainder of the day one unit will shut down, leaving the remaining unit in operation.

There were numerous reasons for the adoption of automatic equipment in Cleveland. Primarily, the company was presented with the necessity of supplying additional power to portions of the city lying within the district wherein, by reason of recent developments and natural traffic growth, the power supply was in some cases inadequate. It was found impractical to attempt to increase the operating potential in most of these territories by additional feeders from existing plants, for not only were feeders necessary, but additional conversion equipment would have to be installed at the various plants to absorb the increased load, together with losses. The alternative was, of course, additional power facilities, located within the territory in which the load originated. The results taken from one of the several surveys made to determine the most economical procedure with respect to a given territory, indicates the following:

<i>Power supplied from existing plants locations</i>		
Proportional part of building, together with new equipment necessary to be installed for the load.		\$ 89,398
Total feeder copper (existing plus additional copper)		274,251
Total.....		325,251
Annual charges.....		53,636
<i>Power supplied for manually operated substations*</i>		
Building, land, equipment and feeders.....		\$221,263
Annual charges.....		44,240
Operation.....	\$ 8,290.	
Feeder losses.....	11,644.	
<i>Power supplied for automatically operated substations</i>		
Buildings, land, equipment and feeders.....		\$242,129
Annual charges.....		39,735
Inspection.....	\$ 400.	
Feeder losses.....	11,644.	
<i>Basis upon which annual charges are calculated</i>		
Buildings	8¾ per cent (Insurance, taxes, depreciation, interest).	
Land	6 per cent (Taxes, interest).	
Equipment	10¼ per cent (Insurance, taxes, depreciation, interest).	
Maintenance	(Buildings, equipment).	
Operation	or Inspector.	
Feeder copper	9 per cent (Taxes, interest).	
Feeder losses	\$11,644.	

*Used for comparison purposes only.

This indicates a net annual saving of \$13,900 comparing the automatic substation with the scheme of supplying the territory from existing plants. In comparing the automatic with the manually operated plant of like capacity an annual saving of \$4500 is indicated in favor of the automatic substation, notwithstanding the fact that \$20,866 increase investment is made. Incidentally, a comparison of the cost of feeders in the first and second plants would emphasize

the relation which this item bears to the economical location of power facilities with regard to load, particularly when working with low voltages. It might be of interest to note that if the present power facilities of the company were all on an automatic basis today, calculation indicates that a saving in operating expense could be made amounting to approximately \$175,000 annually.³

With these possible savings in mind, it remained but to ascertain the reliability of automatic equipment. From operating records available it appeared that this equipment, where properly installed and maintained, was more reliable than the manually operated. From experience this is borne out.

This is easily seen when it is considered that the chances of an operator being able to anticipate trouble are remote. Abnormal conditions develop so quickly and are often so obscure that before he has the opportunity to realize what is occurring the damage is often done, or if not, his principal duty then will be to limit the extent of injury and to confine it to the particular piece of apparatus or circuit in which it originated. While he is so engaged service is, in all probability, at a standstill. With automatic control the equipment is protected as the trouble occurs, and is prevented from spreading. This is accomplished by the various protective devices peculiar to this type of control. Interruptions to service are, therefore, held at a minimum.

No matter how well trained the operators may be, there are certain errors of judgment that must necessarily enter into the operation. In large centers of population, where the tendency normally is for high labor turnover, there will always be a larger percentage of new operators on the system than in some of the less active cities. This element of inexperienced operators will result in operating mishaps, which are avoided by use of automatic control. In connection with the item of labor, there is the intangible but undoubtedly great value obtained in adopting automatic control in the assurance gained by the knowledge that labor difficulties cannot interfere with the success or continuity of service of a system so equipped.

As has been previously mentioned, the installation of the automatic substation in Cleveland, represents the first attempt to utilize this type of equipment in metropolitan service. These stations then represent pioneer work, there being no precedent. Utilizing the experience and knowledge of operating conditions in Cleveland, continuous studies were made of the adaptability of this type of control, as it was being planned, with the result that changes and additions were made in the layout prior to its manufacture, and in fact, while in the process of manufacture. These were necessary to bring the equipment to a point where it would meet with all of the operating conditions and where absolute dependence could be placed upon it under all

3. Comparison made with present system, including steam plant

conditions. The results have been exceedingly gratifying, for aside from the d-c. outgoing feeder control scheme, there have been comparatively few changes found necessary considering the immensity of the problem. Some of the changes necessitating the redesign, addition or rearrangement of relays, while the majority were accomplished by changing circuit connections.

Referring to the control of outgoing d-c. feeders, the solution to this phase has been the most troublesome of the whole development. There was installed and in fact still exists in these stations, a type of feeder control, known as the current limiting resistance method of control, which has met with success in interurban and small city work. At the time of installation it was the only scheme available. With this scheme, in the event of a short circuit or overload occurring on the feeder, the current flow and voltage to the feeder is reduced by inserting the resistance. If this abnormal condition persists, the section is finally cut off from the source of power entirely. This method of operation on the property where a premium is placed upon continuity of service is not acceptable. Recently a new method of feeder control has been devised. This scheme eliminates the current limiting resistance entirely. By the use of a current transformer on the d-c. feeder, an arrangement is secured whereby the feeder will be disconnected only in the event of a short circuit occurring on the feeder. This is a step towards the continuity of service we wish to obtain, however, it still does not fill all the requirements, for, in our desire for continuous service, it is necessary that wherever possible, power must be supplied to faulty feeders for the movement of cars and to clear the feeder of fault. To accomplish this and other phases of operation which are desired, it has been necessary to devise a method of remote control. By utilizing an auxiliary or transfer bus in each station with feeders arranged for automatic transfer on short circuits only, a most flexible system is obtained by the addition of this control. Provisions are had for load shifting in case of severe load congestion, failures of conversion equipment, a-c. feeders, etc. This is accomplished by transferring load to adjacent plants over tie feeders, these same feeders furnishing the means of "burning off" grounds on faulty sections, thus replacing the present current limiting resistance.

A brief outline of the remote control equipment which is at present being manufactured, will be of interest. A dispatcher's office will be established at a centralized point from which there will extend two pairs of telephone conductors to each automatic substation. At the dispatcher's office, arranged in a semi-circular desk, each substation will be represented by a small panel containing a series of telephone lamps behind the customary lenses. On the table of this desk is to be arranged a series of buttons, controlling relays by which

combinations may be set up sending impulses to any particular substation where, it will cause to operate certain relays which in turn perform required changes in the operating conditions of the stations. As these changes take place at the station, the dispatcher is advised by the signal lamps mounted on his desk. These lamps enabling him to ascertain at any time the positions of the controlling relays or contactors at any station. The functioning of these devices by reason of automatic operation will also set up signals at the dispatcher's board. To enable the dispatcher to know the load conditions of the stations, that he may act intelligently in cases of emergency, arrangement is had to duplicate in the dispatching center, continuous loading of each station upon a graphic chart. It might be well to state that this system of remote control does not supersede the automatic substation control in any sense. All the various benefits derived from full automatic control still remain. This system is so arranged that in the event of the remote control becoming inoperative from any reason whatsoever, it is automatically disconnected from the substation control leaving the station still under full automatic control.

The present plan of the railway company contemplates the use of automatically controlled stations for the entire property eventually. It is proposed where practical to break up the existing manually operated stations into units of one and two machines each. With this in mind, the remote control has been designed with facilities for increasing the number of station positions to thirty.

Regarding the future of automatic control: While I have limited myself to the railway applications only, the development has not been limited to this field. Engineers in other fields of electric generation and distribution have not failed to grasp the idea and apply it. There are several installations in 220-volt d-c. Edison service, likewise, there are several industrial applications. The idea has also been utilized in one or two instances in hydro-generating plants. In this particular field automatic control should, it seems to me, have as wide an application as in the railway field, for by the use of this control, thousands of small water power sights are made possible of development and may produce power economically whereas before, this was impossible.

Each and every application of automatic equipment, no matter in what field, will present a variation of control features by reason of new or different operating conditions met with upon each new application, but with the engineering talent and ingenuity displayed by the men heading the control divisions of the principal companies engaged in this particular field, together with the inclination of the engineer in charge of the property to cooperate and study conditions and requirements, the limitations of automatic control are not in sight.

Systems of Single-Phase Regeneration for Use with Series Type Commutator Motors

BY L. J. HIBBARD

Railway Equipment Engineer, Westinghouse Electric & Manufacturing Company, E. Pittsburgh, Pa.

Review of the Subject.—The alternating-current series motor may be adapted to regeneration in a number of important respects more readily than a similar direct-current series motor on account of the following features: (1) The a-c. motor always employs a cross-field winding which prevents armature distortion. (2) A relatively low impressed commutator voltage is used reducing the danger from flashing. (3) With the a-c. system a transformer can be used to obtain desired variation in motor voltage. The advantages of this feature are outlined at length with reference to its effect on regeneration.

The several schemes of regenerative connections are divided into four classes as follows: (1) Series excitation; (2) self-excitation, or cross excitation; (3) shunt excitation; (4) separate excitation. The first two connections have not been commercially used. A number of fundamental assumptions as to the theory of the single-phase motor are given as a basis for vector diagrams, which are used to analyze the conditions for both motoring and regeneration for the four types of connections. A detailed presentation of the conditions which obtain with these connections is then given by the author.

When using the first connection for regeneration it is necessary with series excitation to reverse the main field with reference to the motoring conditions. With the alternating-current series motor a sudden decrease in the line voltage will not increase the regenerated current as in the case of direct current, but will tend to decrease it. In a like manner an increased speed with any given impressed voltage will also decrease the regenerated current. Objectionable characteristics are: first, a strong tendency to pick up as a direct-current generator with the secondary transformer winding acting as a short circuit; second, a like tendency for low-frequency currents to be set up; third, undesirable speed torque characteristics. These features are cited as the reasons for not seriously considering this type of motor and connection for railway application with regeneration in this country.

The second system employs an extra set of brushes located midway between the normal brushes on the commutator. This system is

handicapped by the fact that armatures and also the commutators of the motors must have increased capacity because of the necessity for carrying exciting as well as load currents during regeneration. This is particularly objectionable on account of the space limitations existing in connection with railway application. Another disadvantage is the necessity for extra brushes around the commutator. This method of connection, however, has the advantage of giving a shunt speed torque characteristic and permitting power factor compensation during regeneration.

The third connection using the so-called shunt excitation has the advantage of simplicity and reliability. The chief disadvantage lies in the fact that power factor correction cannot be made during regeneration. It is handicapped to some extent, due to the fact that the same continuous torque between armature and field winding cannot be obtained as was possible with the series connection. In a majority of commercial applications, however, this connection will provide sufficient tractive effort. Only two units are required to obtain regeneration: first a substantial reactor and, second, a change-over switch for controlling the same.

The fourth system utilizes separate exciters either of the (1) constant speed or (2) variable speed type. Under the constant speed systems, either phase converters or motor generator sets may be used. With the variable speed, either separate axle generators or one of the main motors is used as an exciter. This system, although in general requiring more apparatus for regeneration (hence costing and weighing more) than some of the other systems, is also more flexible. The desired speed torque characteristics can be obtained and, with a constant speed exciter, power factor compensation is available as well as power for driving auxiliary apparatus.

The conclusion is reached that regeneration can be properly and successfully obtained with one or more of the several systems outlined. In the several appendices, explanation is made of the vector diagrams by means of which the author analyzes the conditions for each system of connection.

IT has long been known that under certain conditions a motor driving an electric locomotive or car could be converted into a generator and that as such it could be used to exert a braking effect upon the vehicle either for "holding" a train while descending a grade, or for reducing the speed of the train when making a stop.

Numerous articles have appeared in the technical press during the past few years covering various systems of control for use in connection with three-phase, split-phase and direct-current systems of regeneration.

However, practically no mention has been made of systems of regeneration for use with single-phase series type commutator motors.

Probably the reader is better acquainted with the direct-current system at the present time than with any other type. Hence, in the following general discussion the writer will use the d-c. system for comparative purposes.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 14-17, 1923.

The Westinghouse Electric & Manufacturing Company tested a regenerative single-phase locomotive on its test track for several months at East Pittsburgh as long ago as 1905, and a few years later a similar system was applied to the Midi locomotive in France.

At that time there was practically no demand whatsoever for regenerative equipments in the commercial field, and the system referred to above was used primarily in connection with a number of important gear tests which were being made at that time. The regenerative feature was utilized to give a relatively cheap and flexible load, two similar locomotives being used during the test, one regenerating while the other motored.

The a-c. series motor lends itself to regeneration in a number of important respects more readily than the corresponding direct-current series type motor. This type of a-c. motor is always provided with a cross-field winding preventing armature distortion, and as it always has a relatively low impressed commutator

voltage, the danger of flashing is practically eliminated.

The a-c. system also has the advantage that the existence of a transformer on the vehicle makes the variation of motor voltage very simple and economical. This, in turn, means that weakened fields at high speeds are not a necessity and that regeneration at practically all speeds down to a standstill can be accomplished with practically any desired field strength. This permits the obtaining of any desired torque with any desired speed, with the armature and field currents adjusted to give the minimum root mean square currents in either member. Thus, in general, it is possible to effect regeneration with a lower root mean square current in the armature and over a greater range in speed than is possible in the case of the direct-current system with its limited and less flexible voltage range; also, due to the presence of the transformer and due to the fact that connections can be completed inductively, as well as conductively, the a-c. series motor lends itself more economically to a larger number of regenerative connections than appears possible with the d-c. system.

The various schemes of regenerative connections available for use with this type of motor can be divided into four distinct classes, or combinations of these classes, depending upon the type of field excitation employed. The four classes can be designated as follows:

1. Series Excitation
2. Self-excitation, or cross excitation.
3. Shunt Excitation.
4. Separate Excitation.

The third and fourth classes have been commercially applied and detailed description of a few of the various forms of connections possible in these two classes will be given in the following pages.

In so far as is known by the writer, no commercial applications of the first and second classes have been made as yet, and only a general discussion of a single form of each of these two classes will be given.

For the sake of clarity it is necessary to give in a brief manner several fundamental assumptions which will act as a basis for the vector diagrams which follow. In all cases it is assumed that the electrical windings are such that:

1. A motoring torque will be exerted when the field flux and armature current of a given machine have a component 180 deg. out of phase with each other.
2. A braking or regenerating torque will be exerted when the field flux and armature current have a component in phase with each other.
3. Power will be taken from the line when the armature current has a component in phase with line voltage.
4. Power will be returned to the line when the armature current has a component 180 deg. out of phase with the line voltage.
5. A lagging armature current will be taken from, or returned to, the line when the resultant wattless

current required for the armature circuit is lagging.

6. A leading armature current will be taken from or returned to the line when the resultant wattless current required for the armature circuit is leading.

The following well known fundamental laws will be used frequently and are stated in order that the reader may more easily follow the writer's various presentations.

(1) The sum of the voltages in any closed circuit must be equal to zero, that is, the sum of all the counter voltages must be equal and opposite to the impressed voltage.

(2) When a voltage is applied to a reactance, the current produced will lag 90 deg. behind the impressed voltage. The reactive drop, or counter voltage, produced by this current must be 180 deg. away from the impressed voltage in order to produce a balanced condition, and hence the reactive drop must lag 90 deg. behind the current that produces it.

(3) Likewise, when a voltage is applied to a resistance, the current produced will be in phase with the impressed voltage. The RI drop, or counter volts, produced by this current must be 180 deg. away from

FIG. 1—SERIES MOTOR

the impressed voltage in order to produce balance, and hence, it is 180 deg. away from the current.

(4) The counter electromotive force set up, due to a rotating conductor cutting a given flux, will be in phase with the flux cut.

Also, it might be noted that all vector diagrams are arranged so that any leading vector is always drawn counter-clockwise with respect to any lagging vector.

MOTRING WITH SERIES EXCITATION¹

In line with the above the operation of the series motor as a motor assumes the form shown in Fig. 1 which is a schematic of a typical main circuit connection.

The transformer voltage applied across the motor terminals sets up a circulating current in the motor circuit. The motor circuit is inductive and therefore the current lags the impressed voltage. The circulating current thus set up produces a counter voltage equal and opposite to the impressed voltage. At standstill this

1. See Appendix A for detailed Vector Analysis.

counter voltage is composed entirely of the impedance drop around the armature circuit. The impedance drop consists of a resistance and reactance drop. The reactance drop is at right angles to the resistance drop.

FIG. 2—SERIES MOTOR

The resistance drop is 180 deg. away from the armature current and in phase with the field current.

As the speed of the motor increases a counter electromotive force is set up across the armature which adds directly to the resistance drop in the circuit. Hence at any speed except zero the resultant counter

FIG. 3—SERIES GENERATOR

voltage is composed of the counter electromotive force as well as the impedance drop in the armature circuit. As this counter electromotive force grows in value with any given constant impressed voltage the impedance drop and hence the armature current must decrease in value to maintain the proper resultant value of countervoltage. Hence, with a fixed terminal voltage the armature current and consequently the propelling torque, decreases as the speed increases.

Fig. 5 shows the typical shape of the speed torque characteristic obtained with the series connection.

REGENERATION WITH SERIES EXCITATION²

In order to regenerate after motoring with the series

2. See appendix B for detailed Vector Analysis.

connection the main field must be reversed. Thus Fig. 3 shows a typical main circuit schematic for this connection. The operation regenerating is similar to the operation motoring except that the field current, and consequently the field flux and resultant torque produced, has been reversed. Thus at standstill the counter voltages set up are exactly the same as in the motoring connections at standstill. However, as the speed increases from standstill the counter electromotive force set up is in the opposite direction and hence opposes the resistance drop but remains at right

FIG. 4—SERIES GENERATOR

angles to the reactance drop. Thus at some definite speed where the counter electromotive force is just equal and opposite to the $R I$ drop the armature current will lag the line voltage by exactly 90 deg. since the only counter voltage available is the reactance drop around the armature circuit.

At this point the generator is supplying its own losses and hence is drawing no power from the line. As the

FIG. 5—APPROXIMATE "SPEED T. E." CHARACTERISTIC. SERIES EXCITATION

speed increases above this value the counter motive force overbalances the resistance drop resultant counter voltage is equal to the of the reactance drop and the difference is resistance drop and counter electromotive force

resultant vector relations are such that power is returned to the line. This can be readily seen if the difference between the counter electromotive force and the resistance drop is considered as a negative resistance drop. The presence of a positive resistance drop indicates the use of power and hence the presence of a negative resistance drop must represent the generation of power.

Thus it is seen that the alternating-current series motor can be made to operate as a series generator merely by reversing the fields. A suddenly decreased line voltage will not increase the regenerated current of the line frequency as in the case of direct current, but will tend to decrease it. Similarly an increased speed with any given impressed voltage will also decrease the regenerated current. While these characteristics would make its use for regeneration possible, other difficulties have to be overcome for a practical solution along these lines.

The system is handicapped by the strong tendency of the generator to pick up as a direct-current generator with the secondary transformer winding serving prac-

FIG. 6—CROSS FIELD OF SELF EXCITING GENERATOR

tically as a short circuit. Even if direct currents are made impossible, as in the case of a repulsion motor, there is a strong tendency for low-frequency currents to be set up, causing trouble. Also the speed torque characteristics obtained with this connection (See Fig. 5) are not the best type for all classes of regenerative service since the torque tends to decrease as the speed increases for any given value of impressed voltage. In view of these difficulties this method of regeneration has so far not been seriously considered for railway application in this country. Undoubtedly, however, due to its simplicity it has possibilities for the future.

REGENERATION WITH CROSS-FIELD OR SELF-EXCITATION³

A regenerative system of the second kind with the main motors acting as armature (self-excited) generators is shown in Fig. 6. In this system the armature is supplied with an extra set of brushes *b b* which are located around the commutator midway between the normal or motoring set. The cross field is connected across a section of the main transformer. The resultant

current and flux set up in the cross field circuit is approximately 90 deg. behind the line voltage since the field circuit is highly inductive. The armature conductors revolving in and cutting the cross-field flux set up by a counter electromotive force across brushes *b b* in phase with the flux cut and hence at right angles and lagging the line voltage.

This voltage is then connected across the main field and sets up a current and flux through the main field

FIG. 7—CROSS FIELD OF SELF EXCITING GENERATOR

approximately 90 deg. behind voltage *b b* or approximately 180 deg. away from the line voltage. The armature conductors revolving in and cutting this main field flux set up a voltage across the normal brushes approximately 180 deg. away from the line voltage. Hence, when these terminals are connected to the transformer the resultant voltage difference will set up a circulating current in the circuit. If the line voltage impressed is greater than generated voltage a motoring torque will be produced and power will be drawn from the line. If the generated voltage exceeds the line voltage a braking torque will be exerted and power will be returned to the line. The small section of transformer voltage in the excitation circuit is introduced in order to neutralize the resistance drops in both the cross field and main field circuits and hence maintain the regenerated voltage exactly 180 deg. behind the line voltage.

Fig. 8 shows the typical shape of the speed torque

FIG. 8—APPROXIMATE SPEED-TRACTION EFFORT CHARACTERISTIC WITH CROSS-FIELD EXCITATION SYSTEM

characteristic obtained with this connection.

This system is handicapped due to the fact that the armatures, and also the commutators of the main motors, have to be increased in capacity because they carry the exciting currents in addition to the load currents. This is quite a serious handicap in view of the space limitations existing for the main motors in con-

3. See appendix C for Vector Analysis.

nection with railway work. Another disadvantage of the system is the necessity of additional brushes around the commutator.

However, such a system is advantageous in so far as it gives a shunt or flat speed-torque characteristic (see Fig. 8) and as it permits of power factor compensation

FIG. 9—SHUNT GENERATOR

during regeneration, and possibly during motoring, within certain limits. Hence, it eliminates the necessity of auxiliary rotating apparatus that otherwise might be required to obtain this power factor compensation feature and therefore probably has certain possibilities for the future.

REGENERATION WITH SHUNT EXCITATION⁴

The simplest form for a shunt type regenerative system is shown in Fig. 9. The main fields are connected

FIG. 10—VARIABLE SPEED—REGENERATING. CONSTANT IMPRESSED ARMATURE VOLTS. SHUNT EXCITATION. CONSTANT IMPRESSED FIELD VOLTS

directly across a section of the main transformer. The resulting field current and flux set up in the circuit lags approximately 90 deg. behind the line voltage. The armature conductors revolving in and cutting the field

flux set up a counter electromotive force across the armature circuit in phase with the flux cut and hence approximately 90 deg. behind the line voltage.

The armature is thus connected in series with an

FIG. 11—REGENERATION—CONSTANT SPEED—VARIABLE IMPRESSED ARMATURE VOLTAGE. SHUNT EXCITATION

external reactor and across a section of the main transformer. The vector sum of the counter electromotive force generated in the armature and of the voltage impressed across the armature give a resultant voltage in the armature circuit which lags behind the line volt-

FIG. 12—MOTRING—VARIABLE SPEED—CONSTANT IMPRESSED ARMATURE VOLTS. SHUNT EXCITATION, CONSTANT IMPRESSED FIELD VOLTS.

age by some angle depending upon the relative values of the impressed and generated voltages: This resultant voltage sets up a circulating current in the armature circuit which lags by approximately 90 deg. since

4. See appendix D for Vector Analysis.

the armature is highly inductive due to the external reactor. Hence, since the field current and flux are also lagging the line voltage the armature current has a component in phase, the field flux, and is therefore exerting a braking torque. Also, due to the fact that the resultant voltage in the armature circuit lags the line voltage and to the fact that the armature current is approximately 90 deg. behind this voltage, the armature current must lag the line voltage by more than 90 deg. hence will have a component 180 deg. away from it. Thus, power will be returned to the line.

If the main fields are reversed in the above connections, the counter electromotive force produced will be

FIG. 13

reversed. This will shift the resultant voltage in the armature circuit by 90 deg. and likewise the armature current.

The resultant voltage will lead the line voltage while the armature current will lag the line voltage, by something less than 90 deg. depending upon the relative values of the line voltage and the counter electromotive force. Hence a motoring torque will be produced and power will be drawn from the line.

Fig. 13 (A, B, and C) gives the typical shape of the different speed torque characteristics for both motoring and regenerating obtainable with this connection.

The chief handicap of this system lies in the fact that it does not permit of power factor correction during the regenerating period and must always draw a result-

ant wattless component of current from the line for excitation. It is also handicapped to some extent due to the fact that the same continuous torque between the armature and field windings, possible with the series connection, cannot be obtained in the shunt connection due to the phase difference between the armature current and field flux inherent with this connection. However, in practical applications sufficient torque can be developed between the windings

FIG. 14—REGENERATION—MODIFIED SHUNT EXCITATION

such that when added to the losses the resultant retarding effort available will be more than sufficient for holding any train while descending a given grade that can be hauled up the same grade with the series connection. Also, when the obtainable torque is not sufficient for any given application the speed-torque characteristics can be adjusted easily and properly for parallel operation with the airbrakes on the train. Hence, this connection will provide ample tractive efforts for a large majority of the future commercial applications.

The connections and control are simple and reliable. Practically only two units are added to the normal motoring control apparatus, these units consisting of a simple substantial reactor and a simple change-over switch for controlling the reactor. The speed torque

Figure 15.

FIG. 15—REGENERATION—MODIFIED SHUNT EXCITATION

characteristics available cover practically the entire range from (1) a vertical curve, that is constant torque at all speeds, (see Fig. 13A) which is ideal for straight deceleration purposes, to (2) a shunt or relatively flat curve, that is increasing torque with increasing speed, (see Fig. 13C) which is the desirable characteristic for use in holding a train at some given desired speed when descending a grade.

Hence, this form lends itself readily to practically any class of service and will undoubtedly be in great demand for future commercial applications.

A modified form of the shunt connection is shown in Fig. 14 and is described in appendix D.

SEPARATE EXCITATIONS⁵

The regenerative systems utilizing separate exciters during the regenerating period can be divided into two general classes as follows:

1. Constant Speed Exciter Systems
 - (a) Phase Converters
 - (b) Motor Generator Sets.
2. Variable Speed Exciters
 - (a) Separate Axle Generators.
 - (b) Main Motor as an Exciter.

In the following a description will be given of a constant speed exciter system using a phase converter as

FIG. 16—REGENERATION—CONSTANT SPEED EXCITER SYSTEM
an exciter. A variable speed exciter system using one of the main motors as an exciter will be described in appendix E.

A constant speed exciter system is shown in Figs. 16 and 17. In this system the phase converter or exciter is essentially a two-phase synchronous or induction motor running on single phase. Hence, a voltage is generated across the second or open phase at right

FIG. 17—REGENERATION—CONSTANT SPEED EXCITER SYSTEM
angles to the line voltage impressed across the motoring phase. In most applications of this type a two phase synchronous motor will probably be employed in order that it may be operated as a synchronous condenser during the motoring period for power factor correction. Also, with the use of the direct-current excitation in the rotor the main motor field excitation can be supplied in part if not entirely without drawing it all in the form of wattless lagging current from the line.

The right angle voltage obtained from the generating phase of the phase converter is connected in series with

5. See appendix E for Vector Analysis.

the main field of the traction motor and across a section of the main transformer. The vector sum of these two voltages gives a resultant voltage which sets up a field current and field flux through the field circuit. The resultant field voltage lags the line voltage by some angle depending upon the relative values of transformer voltage and phase converter voltage employed. The resultant field current and field flux lag behind this

FIG. 18—REGENERATION—VARIABLE SPEED EXCITER SYSTEM

voltage by 90 deg. since the field circuit is highly inductive, and therefore lags behind the line voltage by more than 90 deg.

The main armature conductors revolving in and cutting this flux set up a counter electromotive force across the armature in phase with the flux cut. The vector sum of this counter electromotive force and of the transformer voltage impressed across the armature gives a resultant voltage which sets up circulating current in the armature circuit. The armature current lags the resultant armature voltage by some angle

FIG. 19—REGENERATION—VARIABLE SPEED EXCITER SYSTEM

depending upon the relative values of the resistance and reactance drops through the circuit.

By the proper manipulation of the transformer voltages impressed across the main field and armature circuits (and when desired, the phase converter) the circulating armature current can be given a leading or lagging component 180 degrees away from the line voltage, and at the same time exert a braking torque, or it can be given a leading or lagging component in phase with the line voltage, and at the same time exert a motoring torque. Thus all requirements for regeneration can be fulfilled.

Figure 20A shows three different typical approximate forms of speed torque characteristics, not drawn

scale, obtainable with this system of regeneration. It is possible to obtain a family of curves for practically any desired form of characteristics, by the proper manipulation and choice of the various applied voltages. In fact, with the proper control facilities, it is possible to change from any one family to one or more different families of curves, during the regenerating period. Thus, it is possible to choose the proper form of curve most suitable for each of the various forms of regenerative duty that may be encountered over any given profile. Hence, on grades on which it is necessary to use the air brakes on the train in conjunction with regeneration, in order to hold the train at some desired speed or speeds, a proper family of curves suitable for parallel operation with air brakes can be selected.

As the steepness of the grade decreases and the regenerative torque available is sufficient for holding the train at the desired speed, without the aid of air brakes, a family of curves most suitable for this service

the same continuous torque at the air gap as is obtainable in the series motor connection. Also in this system the constant speed exciter can be utilized for power factor compensation as well as driving auxiliary apparatus during the motoring periods.

Hence, this system, in one or more of its possible forms, will also undoubtedly be used to a large extent in future commercial applications and especially where extremely heavy torque regenerative duty is required.

CONCLUSION

In general, it can be safely stated that probably any future regenerative application that may be desired, can be properly and successfully taken care of with one or more of the various single-phase systems available at the present time.

As a whole the systems are so flexible that the selection of a particular system for any given application can probably be governed in the main by the requirements of the particular application only, and can be chosen to best suit the requirements of that application.

Appendix A

MOTRING WITH SERIES EXCITATION:

The clock diagram for the series motor, operating as a motor, assumes the following simple forms, (see Figs. 1 and 2).

In Fig. 2A, E_{L1} represents the voltage that must be applied across the motor terminals at standstill to set up a current I_a through the motor circuit. The motor circuit is inductive and, therefore, the current lags the impressed volts. The motor is drawing power from the line (equal to the losses in the motor circuit only at standstill), and hence has a component in phase with the line voltage, and since it is exerting a propelling torque, it is 180 degrees away from the field current I_f and field flux ϕ_f .

The counter-voltage at standstill is composed entirely of the impedance drop around the motor circuit, which in turn represents the vectorial sum of the resistance and the reactance drops.

In Fig. 2B, E_{L2} represents the voltage that must be applied across the motor terminals at approximately one-half speed to set up the same current I_a . E_{L2} is greater than E_{L1} due to the fact that the impressed voltage must overcome the back electromotive force of the motor E_{c2} , as well as the impedance drop around the circuit. As E_c grows in value due to speed with any given impressed voltage, the impedance drop and hence the armature current must decrease in value to give the correct vector sum of counter-voltages.

In Fig. 2C, E_{L3} represents the voltage that must be applied across the motor terminals at full speed to set up current I_a . E_{L3} is greater than E_{L2} , due to the fact that E_{c3} is greater than E_{c2} .

The power component of current I_a in Fig. 2B and Fig. 2C is greater than the corresponding component in Fig. 2A, due to the fact that the motor is delivering power, hence must draw power from the line.

FIG. 20

can be obtained. Then again when it is desired to decelerate the train from some given speed to standstill, the family of curves most suitable for such service can be chosen. Thus this system, although in general requiring more regenerative apparatus, (and hence costing and weighing more), than some of the previously described systems, is also more flexible and hence will also do more than these systems. The control and apparatus required for regeneration are relatively simple and reliable.

The proper speed torque characteristics can be obtained for practically any application and if desired power factor correction during the regenerating period can be easily obtained.

In the constant speed exciter systems the value of torque obtainable is limited by the current capacity of the motor windings only and hence, if desired will give

It should be noted that in both Fig. 2B and 2C the counter electromotive force E_c and the $R I$ drop are added directly and their resultant added vectorially to the $X I$ drop. When the series connection is utilized for regenerative purposes, it so happens that E_c and the $R I$ drop are subtracted from each other and the net resultant thus obtained is then added vectorially to the $X I$ drop.

Appendix B

REGENERATION WITH SERIES EXCITATION

In order to regenerate with the series connection after motoring, the main fields must first be reversed. The clock diagram for this connection then assumes the simple form shown in Figs. 3 and 4.

E_{L1} represents the voltage that must be applied across the motor terminals at standstill to set up a current I_a through the generator circuit. By referring to Fig. 2A for the series motor, it will be seen that the clock diagram for the series motor at standstill is exactly the same as the clock diagram for the series generator at standstill, except that the field current I_f and field flux ϕ_f have been reversed.

However, as the generator begins to pick up speed as it is propelled down the grade by the weight of the train, the counter electromotive force built up in the armature begins to counteract the resistance drop in the generator circuit until at some speed N , the counter electromotive force (see Fig. 4B), is just equal and opposite to the $R I$ drop. At this point the armature current has swung around until it lags the line voltage by exactly 90 deg. This means that the generator is drawing no power from the line whatsoever, and hence at this speed it is supplying its own losses.

As the speed of the train still further increases, the counter electromotive force set up in the armature circuit increases; hence, E_{L3} , Fig. 4C represents the voltage that must be applied across the generator terminals at full speed to set up the current I_a through the armature circuit.

E_{c3} represents the difference between the counter electromotive force generated in the armature circuit at this speed and the resistance drop through the circuit, due to I_a . The vector sum of E_{c3} and $X I_a$ is equal and opposite to E_{L3} and, hence a balanced condition exists. The current I_a has a component 180 degrees away from the line voltage, and hence it is delivering power to the trolley. Also, the current I_a is in phase with the field flux ϕ_f , and hence the generator is exerting a braking torque.

It should be noted that as the speed, and consequently the counter electromotive force in the armature circuit increases, the line voltage must also increase in order to maintain the same value of I_a otherwise as the counter electromotive force increases, due to increased speed, the $X I$ drop and consequently the current I_a would have to decrease in order to maintain the proper counter-voltage.

Hence, with a fixed terminal voltage, the armature current and consequently the retarding torque, decreases as the speed increases.

Thus, Fig. 5 shows the typical shape of the speed-torque characteristics obtained with the series connection.

Appendix C

REGENERATION WITH CROSS-FIELD OR SELF-EXCITATION

In this system, the armatures must be supplied with an extra set of exciter brushes as shown in Fig. 6. The operation of this system is as follows: (see Fig. 7).

Assume that with the motors rotating at a certain speed, the cross field circuit is connected to a line voltage T_1 . It is evident that a cross field will be set up, the size of which is essentially governed by the number of cross field turns and the voltage impressed upon the cross field. The cross field current I_c and flux ϕ_c lag behind the line voltage E_L by approximately 90 degrees, since the field is highly inductive. This cross field will induce by rotation a voltage E_x between the exciter brushes $b b$, which is proportional to and in phase with the cross field, and hence also lags behind the line voltage by approximately 90 degrees.

This voltage is then connected in series with a small section of the main transformer voltage T_2 , and the resultant voltage E_o , is connected across the main fields. Since the main field circuit is highly inductive, the field current I_f and flux ϕ_f will lag behind the resultant excitation voltage E_o by approximately 90 deg., and hence will be approximately 180 deg. away from the line voltage T_1 . The small section of transformer voltage T_2 in the excitation circuit is introduced in order to counteract the effect of the resistance drops in both the cross field and main field circuits in such a way as to cause the main field flux to lag the line volts by exactly 180 deg. The main field thus set up will, therefore, induce by rotation a voltage E_c across the armature terminals 180 deg. away from the line voltage. The value of this generated electromotive force can easily be adjusted by regulating the voltage impressed upon the cross field circuit, and hence can be made sufficiently in excess of the impressed armature voltage E_L so that a leading regenerated current I_a will be returned to the line. Also, since I_a has a component in phase with ϕ_f , a braking torque will be exerted. Hence, all requirements for regeneration are fulfilled by this arrangement.

Appendix D

REGENERATING WITH SHUNT EXCITATION

The simplest form of connections for a regenerative system of the third kind is shown in Figs. 9 and 10. In this system the main field is connected directly across a section of the transformer voltage T_1 and the armature is connected in series with a current limiting and phase-shifting reactor D , and across a section of the transformer voltage E_L .

reactors are decreased by an amount equal to the value of main field reactance utilized in the various armature circuits.

The chief disadvantage lies in the added control complications entailed due to multiplication of the armature circuits.

Appendix E

REGENERATION—SEPARATE EXCITATION

The clock diagram for the regeneration system using a phase converter as an exciter is shown in Figs. 16 and 17.

Referring to Fig. 16, it is seen that a voltage T_1 is applied across the motoring phase A of the phase converter. This induces a voltage E_x across the open or generating phase B . This generating phase voltage E_x is connected in series with a section of the transformer voltage T_2 and the resultant voltage E_1 thus obtained is connected across the main field of the main traction motor. This voltage E_1 sets up a field current I_f and field flux ϕ_f through the field circuit. I_f and ϕ_f lag the voltage E_1 by approximately 90 deg. since the main field is highly inductive.

The armature conductors revolving in and cutting ϕ_f set up a counter electromotive force E_c across the armature circuit in phase with the flux cut. The vector sum of E_c and E_1 gives a resultant voltage E_o which sets up a circulating current I_a in the armature circuit. I_a lags E_o by some angle θ depending entirely upon the relative values of the resistance and reactance drops in the armature circuit. I_a has a component of current 180 deg. away from line voltage and hence power is being returned to the line. Also I_a has a component in phase with ϕ_c and hence a braking torque is being exerted. Thus all requirements for regeneration are being fulfilled.

A variable speed exciter system is shown in Figs. 18 and 19. This system is only feasible when there are two or more main motors available for regenerative duty. In this system the main field of No. 1 motor is connected across some section of transformer voltage T_1 and the armature of the same motor is connected in series with

the main field of motor No. 2 and across a section of the main transformer T_2 . The armature of motor No. 2 is then connected across a section of transformer voltage E_L .

The voltage T_1 sets up a current I_{f1} and flux ϕ_{f1} through the field circuit. The armature conductors of No. 1 motor revolving in and cutting ϕ_{f1} set up a counter electromotive force E_{c1} across the armature. The vector sum of E_{c1} and T_2 or E_1 sets up a circulating current I_{1a} or I_{f2} and flux ϕ_{f2} through the field circuit of No. 2 motor. I_a or I_{f2} and ϕ_{f2} lag behind E_1 by approximately 90 deg. since the field circuit is highly inductive. The armature conductors of motor No. 2 revolving in and cutting ϕ_{f2} sets up a counter electromotive force E_{c2} across No. 2 armature. The vector sum of E_{c2} and E_L or E_o sets up a circulating current I_{2a} in this circuit. I_{2a} lags E_o by some angle θ depending entirely upon the relative values of the resistance and reactance drops in No. 2 armature circuit. The vector sum of I_{1a} and I_{2a} or I_a has a component 180 deg. away from line voltage and hence power is being returned to the line. Also I_{1a} has a component in phase with θ_{f1} and I_{2a} has a component in phase with ϕ_{f2} and hence both motors are exerting a retarding torque. Thus all requirements for regeneration are again fulfilled.

It is interesting to note that the main motor acting as an exciter is not only furnishing the excitation for the other motor but it is also regenerating, that is, it is exerting a braking torque and is returning power to the line. This feature is radically different from the similar type of direct current system. In the direct current system where one of the main motors is used as a generator the motor acting as an exciter returns no power to the line whatsoever and the braking torque exerted is due to the losses in the excitation circuit only. The above feature is due to the fact that the excitation circuit connections, that is, No. 1 motor connections, are essentially the same as those used for straight shunt regeneration, the main field of No. 2 motor serving as the reactor.

Fig. 20B shows the approximate forms of the speed torque characteristics, not drawn to scale, that may be obtained with this type of system.

saturation curve, and to "test" a synchronous generator or motor before it has been actually built. (2) In some applications to take the place of an involved analytical theory; it is often difficult to investigate analytically or numerically the effect of separate factors upon the resultant performance characteristics, especially with considerable saturation. (3) For some purposes to take the place of various proposed circle diagrams which, with a saturated magnetic circuit, are of more than doubtful value and accuracy. (4) To add the judgment of the eye and the skill of the hands to the purely mental ability in selecting the constants of a machine for a desired performance, or in judging the characteristics for assumed constants. (5) To enable an investigator or a student to familiarize himself with a machine as if he had one available for tests.

FIG. 1—A GENERAL VIEW OF THE BLONDELION

This is of particular importance with large or special machines, for which no facilities may be available for testing under full-load conditions.

The Quantities which Can be Represented on the Blondelion. Current, terminal voltage, internal voltage (or the stator flux), input, output, power factor, internal phase angle, synchronizing torque, and the field current. These quantities may be obtained at a constant applied voltage, at a constant input (or output), or at a constant field excitation, as desired; or else, these factors may be varied in any desired manner.

The Factors Which May be Taken Into Account and Varied Separately at Will in the Blondelion. Per cent armature resistance and reactance; the direct and the transverse armature reaction; the degree of saturation in the magnetic circuit; the field ampere-turns; the copper and core losses; friction and windage.

Other Kinematic Devices. The Blondelion is one of the several kinematic devices developed by the writer, for representing the performance characteristics of

various kinds of electrical machinery and lines. The other devices are as follows:

1. A device for imitating the performance of an electromagnetic clutch used in the Owen magnetic car; *Sibley Journal of Engineering*, Jan. 1918, Vol. XXXII, p. 55.

2. The Secomor, a device which imitates the performance of a polyphase series-connected commutator motor; A. I. E. E. TRANS., 1918, Part 1, Vol. XXXVII, p. 329.

3. The Indumor, a device which imitates the performance of a polyphase induction motor; also its modification, the Secomor, which represents the performance of a shunt-connected polyphase commutator motor; A. I. E. E. JOURNAL, 1922, Vol. XLI, p. 107.

4. The Heavisidion, a device which represents the operating characteristics of an electrical transmission line with distributed capacitance and leakage A. I. E. E. JOURNAL, 1923, Vol. XLII, p. 127.

5. The C. P. S'er (named for Dr. C. P. Steinmetz), a device for the automatic addition of impedances in series and admittances in parallel. (in preparation).

6. An Intergraph based on the author's parallel double-tongs, for a mechanical integration or differentiation of a given curve. This device finds its usefulness in problems of hunting of electrical machinery, fly-wheel design, ship stability, etc. *Optical Society of America and Review of Scientific Instruments, Journal* 1922, Vol. VI, p. 978.¹

Limits of Rating and Output. Like any other graphical device, the Blondelion requires certain scales to be chosen for each particular problem. A convenient scale has to be selected for volts, another for armature amperes, still another for the field current, etc. The device can therefore represent the performance of a small machine as well as of one whose output runs into tens of thousands of kilowatts; of a 110-volt machine as well as of one wound for 22,000 volts. As in any graphical device, there are some limitations due to a finite length of the bars and to an interference of the links in certain positions. With one setting the device can be made to give an accurate performance for all values of practical interest, say between one-quarter full-load and twice the full-load, and between 60 and 100 per cent power factor. For points beyond these limits some bars may have to be replaced or a different scale selected.

B. GENERAL DESCRIPTION OF THE BLONDELION

The first complete Blondelion, shown in Fig. 1, was built in the writer's experimental shop, in Cornell University, during the winter of 1921-22. The same device is represented by a single-line diagram in Fig. 2; the construction details are shown in Figs. 6 to 9. Most parts are made of flat steel bars, or of celluloid bars, not over two centimeters wide and a few milli-

1. For a description of the parallel double tongs see the *American Machinist*, 1921, Vol. 55, p. 1050.

meters thick. Some bars are of constant lengths, others are of adjustable useful lengths, holes being drilled every few millimeters. Most bars are connected to each other by means of pivot joints. Some points are constrained to move along straight or curved guides.

The device is assembled on a table provided with a groove XX (Fig. 2.) A stationary rail HH supports the free end of the main bar OT which can turn about O as a center. The bar OT is provided with a longi-

are marked 1, those immediately above them are marked 2, etc. The particular sequence selected is not essential since the device is intended to represent a vector diagram in a plane.

A detailed description of the functions of the different parts of the Blondelion is given below, in connection with its theory. It suffices to state here that the device is set for chosen design constants and for a desired shape of the no-load saturation curve. The setting consists

FIG. 2—A SINGLE-LINE DIAGRAM OF THE BLONDELION

tudinal slot which serves as a guide for the slide FF , roller S , linkage OQG , T -square tt , and the linkage GKC . By means of the T square tt , the bar pp' is made to remain at right angles to the bar OT . The proportional dividers $ANCD$ are guided by pp' at D .

Different bars are placed in different horizontal planes to enable them to cross each other without interference. In Fig. 2 the bars nearest to the table

(a) in the selection of a suitable scale for volts, (b) in the selection and adjustment of a proper curve plate (or plates) to correspond to the desired saturation curve and (c) in the adjustment of the lengths of a few bars. The Blondelion then represents vectorially the following four simultaneous relations which together characterize the machine:

- (a) The voltage drop in the armature winding.
- (b) The component induced e. m. fs.

based, is identical with that in Fig. 3, except that the ohmic drop $i r$ is neglected, since in usual 25- and 60-cycle alternators of medium and large size its value is small as compared to $i x$. This simplifies the construction of the device, although $i r$ could be taken into account, as in the Indumor. The direction of the terminal voltage, e , is taken along the X -axis. The current vector is omitted, since $B D$, $D C$, and $B C$ are proportional to the current, and any of the three may be taken as a measure thereof. In interpreting the diagram, it must be remembered that $B D$, considered as the armature current, is turned ahead by 90 degrees,

FIG. 4—AN ALTERNATOR DIAGRAM AS REPRESENTED BY THE BLONDELION

while as the reactive drop it is in its true phase position. The same remark applies to $D C$.

The direct armature reaction, being proportional to $i \sin \psi$, is also proportional to $G C$, since $C D$ is proportional to the current, and the angle at D is equal to ψ . However, the coefficient of proportionality of the direct armature reaction (Magnetic Circuit, p. 153, eq. 79), is different from that of the transverse reaction; moreover, the direct reaction, M_d , is expressed in ampere-turns, while the effect of the transverse reaction is taken into account by means of the e. m. f. E_t . For these reasons the direct armature reaction is represented not by $G C$, but by $G K = M_d$. In the Blondelion, the ratio of $G C$ to $G K$ may be adjusted at will and then kept constant for any setting corresponding to a given machine.

Let furthermore $S G = M_n$ represent the net field excitation necessary for inducing the net e. m. f. $O G = E_n$. Then the actual number of ampere-turns, M_f , on the field poles must be equal to the sum of M_n and M_d , since the amount M_d is counterbalanced by the direct armature reaction. The values of M_n , M_f and E_n are taken from the no-load saturation curve, but this curve should be corrected for a greater mag-

netic leakage at full load; this is actually done by careful designers.

We thus see that the various linkages of the Blondelion must be such that with any setting for a given machine, the following four vectorial relationships be fulfilled:

(a) The geometric sum of the terminal voltage e and the reactive drop $i x$ must be equal to the total induced e. m. f. $O D = E$.

(b) The sum of the induced e. m. fs. E_n and E_t must be equal to the same induced voltage $O D = E$. Besides, E_n and E_t must remain in quadrature with each other, and both must have the values imposed by the field excitation and the armature reaction.

(c) The length $D C$ must remain proportional to $B D$ and be in line with it, both $B D$ and $D C$ being proportional to the armature current. $G K$ must remain proportional to $G C$.

(d) The field excitation M_f , corrected for the effect of the direct armature reaction M_d , must be equal to the net excitation M_n which corresponds to E_n on the no-load saturation curve of the machine. The proper relationship between M_n and E_n must be preserved at all loads, and the effect of a variable saturation correctly taken into account.

D. THE KINEMATIC DETAILS OF THE BLONDELION

Having established the necessary relationships which must exist between the vector diagram in Fig. 4 and the linkages in Fig. 2, it remains to show how the various points of the device are constrained to move along certain paths in order that the above-mentioned four conditions remain fulfilled with any desired setting.

I. THE SATURATION DEVICE

The saturation device (lower part of Figs. 1 and 2) is that component mechanism of the Blondelion which

FIG. 5—NO-LOAD SATURATION CURVES OF DIFFERENT MACHINES REPLOTED TO A STANDARD SCALE

permits to vary simultaneously the induced voltage E_n and the corresponding field current, or the m. m. f. M_f , in accordance with a chosen no-load saturation curve of the machine (Fig. 5). In order to simplify the construction and the use of the device, it is convenient to replot to a standard scale a given no-load saturation curve, to be used in the Blondelion. In the particular instrument shown in Figs. 1 and 2, the induced voltage E_n is represented by the length $O G$ of five rhombi,

while the corresponding excitation, on the straight part of the saturation curve, is represented by that of the two rhombi, $Q G$. Therefore, the no-load saturation curve must be plotted to such a scale that on its straight part, when the field excitation is represented by say a cm., the corresponding voltage is represented by $(5/2)a$ cm. Moreover, with the chosen dimensions of the device, it is convenient to select such a voltage scale that, for the rated voltage, $O G$ is equal to about 45 cm.

In Fig. 5 the point n corresponds to a rated voltage of 45 cm. and to a field m. m. f. of $(5/2)45 = 18$ cm. With these assumptions, the extended straight parts of all no-load saturation curves pass through the same point n , and the only difference lies in the upper curved parts of these curves. An actual study of many saturation curves showed that the differences in the upper parts, when re-plotted to a standard scale, are comparatively small, so that a setting within wide limits is possible with only three curve plates.

The saturation device (Fig. 2) is mounted on the slotted bar $O T$, pivoted at O . A rhombic articulated lattice $O G$ may be expanded and contracted along the bar $O T$, and the length $O G$ represents the net induced e. m. f. E_n (Figs. 3 and 4). When $O G = 45$ cm., $G Q = (2/5) \times 45 = 18$ cm. Therefore, with this particular setting, $G Q$ represents the excitation corresponding to point n in Fig. 5. In other words, as long as the machine operates on the straight part of the saturation curve, the above described linkage, contracted or expanded, gives the correct relationship between the induced voltage and the field current.

In order to take care properly and automatically of the upper curved part of the no-load saturation curve, the linkage $a b c$ is added, with rollers S and S' . The roller S is guided by the bar $O T$, the roller S' runs along the curved plates P . A tension spring h , between a and b , causes the roller S' to press against the plates P . These plates are supported by the slide $F F$ which is fastened to the rhombic linkage at Q and can move along the bar $O T$ in ball bearings. In order to represent synchronous machines with low, medium, and high saturation, a set of three curved plates is provided. Parts of these plates are combined by trials to form a desired saturation curve. Any plate can be turned into a desired position and fastened with the set screw q . Furthermore, the point of attachment and the length of the link c are adjustable. Actual experience shows that by properly setting the plates, by using the right portions of their edges, and by correctly adjusting the link c , any reasonable saturation curve can be duplicated with sufficient accuracy.

The excitation corresponding to the voltage $O G$ on the upper curved part of the no-load saturation curve is no more represented by the length $G Q$, but by $G S$. The arrangement is such that when $O G$ is short, points Q and S coincide and move together, giving the straight part of the saturation curve. As $O G$ increases in length, the slide $F F$, by virtue of its connection at Q , is forced upward. Hence, the curved plates move up-

wards, allowing the roller S' to move to the left and to change the position of S . The shape of the curves is such that the distance $S G$ varies as the exciting current, or as the ampere-turns M_n , when $O G$ varies as the induced voltage E_n .

In some applications it may be desirable to make the field excitation scale independent of the voltage scale, and not to use always the same point n (Fig. 5). This can be done by adding a separate adjustable linkage $l Q' l'$ (Fig. 2) which can be attached to the main rhombic linkage at any desired place, by means of tapped holes and screws, as in Fig. 6. The plate $F F$ is then attached to Q' , instead of Q , and the roller S must coincide with Q' on the straight portion of the no-load saturation curve.

FIG. 6—PROPORTIONAL DIVIDERS FOR THE REACTANCE DROP AND FOR THE TRANSVERSE ARMATURE REACTION

II. THE PROPORTIONAL DIVIDERS FOR THE REACTANCE DROP

In Figs. 2, 3, and 4 both $B D$ and $D C$ are proportional to the armature current, and therefore, for a given machine, their ratio must be kept constant for all values of the current, that is, for all possible settings of the device. The proportional dividers used for this purpose are shown in Fig. 6, the corresponding points being denoted by the same letters as in Fig. 2. The dividers consist of four members; the bars $A N$, $C N$, and $D M$ are of the same length; the bar $D M$ is of about half their length. An extra linkage, $C_2 C_1 N'$ may be added if so desired, to have the current represented by a separate vector $A C_1$. However, the distances $A D$, $A C$ and $D C$ are all proportional to the current, so that it is only a matter of the scale.

By opening or closing the dividers, the distance $A C$ may be varied at will, and the distances $A D$ and $D C$ always remain proportional to it. To enable the ratio of $A D$ to $D C$ to be set in accordance with the constants of the machine, holes are drilled and tapped in all the bars, as shown in the detail sketch. Countersunk machine screws are used for fastening the bars together at the desired points; these screws do not prevent free rotation of the bars relatively to each other. The point D is provided with a pivoted guide shown in the detail sketch; the cylindrical bar $p p'$ (Figs. 2 and 7) can move freely through this guide. The purpose of the bar $p p'$ is to complete the vector polygon $O B D G$ (Fig. 4).

The bars $A N$ and $C N$ must be long enough to allow the dividers to open for the highest desired value of the armature current. The shorter bar and the holes along the bars must allow of a setting for the highest percentage of reactance drop and of transverse armature reaction that may be encountered under the extreme practical conditions. To illustrate, let the length of the vector $O A$ of the rated terminal voltage be 45 cm., and let, for a machine of normal characteristics, the sum of the reactive drop $i x$ and of the voltage E_t (Figs. 3 and 4), at the rated armature current, be say 50 per cent of the terminal voltage. Then, if performance characteristics are desired up to twice the full-load current, the length $A C$, with the dividers fully opened, should be not less than 45 cm. The lengths of the bars in the above described dividers allow an opening of 70 cm., so that the device can be used either for a heavier overload or for machines of much poorer voltage regulation. For a special machine, or under some extreme conditions, for example for a reactive self-exciting machine without d-c. excitation, an entirely different voltage scale may have to be selected.

If it is desired to take the ohmic drop into consideration, the generalized proportional dividers may be used, similar to those described in the author's paper on the Indumor (see reference above).

FIG. 7—T-SQUARE FOR THE DIRECT AND THE TRANSVERSE ARMATURE REACTION

III. THE PROPORTIONAL DIVIDERS FOR DIRECT ARMATURE REACTION

In the description of Fig. 4 it has been explained that the direct armature reaction, $M_d = G K$, is proportional to the length $G C$. In order to realize this relationship in the Blondelion, rhombic proportional dividers are used, with centers at C , K , and G (Fig. 2). These dividers are independent of the rhombic linkage $O G$. In their general construction the dividers $G K C$ are similar to those shown in Fig. 6. The sides of one of the rhombi are provided with holes (Fig. 1) for adjusting the ratio of $G C$ to $G K$ for a given machine. The total field excitation, M_f , is proportional to the length between the points S and K , and is measured on a centimeter scale placed between these points. When the performance is desired at a constant field current,

a link of constant length may be placed between these points.

IV. THE SLOTTED T-SQUARE FOR KEEPING THE DIRECT AND THE TRANSVERSE REACTION AT RIGHT ANGLES TO EACH OTHER

It has been explained in the description of Figs. 3 and 4 that with any setting of the device the vectors $O C$ and $G D$ must remain perpendicular to each other. This is obtained by means of the T-square $t t'$ (Figs. 2 and 7) fastened to the round rod $p p'$. The T-square is made of sheet brass. Its shorter arm is pivoted at G and its longer arm is guided in the direction $O G$ by the roller pin t' of the rhombic linkage $O G$. The T-square and the rod $p p'$ are fastened together by means of pins f and f' and the pivot G (Fig. 7). At D (Fig. 2) the rod $p p'$ passes through a guide, shown in the detail sketch in Fig. 6. The T-square is shown in Fig. 1 with the right-hand side of its shorter arm cut off. The T-square and the bar $p p'$ are in different planes above and below the main bar $O T$, so as to allow the slide at D to move over the whole length of the bar $p p'$ without interference with the pivot G or with the pins f and f' . The main bar $O T$ can therefore cross all the other bars.

V. THE ARMATURE CURRENT, THE TERMINAL VOLTAGE, AND THE PHASE ANGLE

As is explained above, the magnitude of the armature current is proportional to the opening of the proportional dividers $A C$ (Figs. 2 and 6). The length $A C$ can be measured on a centimeter scale (Fig. 8) pivoted at A and constrained to slide in the sleeve g at C . The A end of the scale is made into an indicating pointer by means of which the phase angle (or the power factor) of the current can be read off directly on the protractor. Since in the Blondelion the current vector is turned by 90 deg. with respect to its true position, the terminal voltage and the current are in phase, when the bar $A C$ is perpendicular to the axis $X X$. For this reason 0 deg. and 100 per cent power factor are marked in the center of the protractor.

The terminal voltage $e = O A$ (Fig. 4) is measured on the centimeter scale $k k$ (Fig. 8) which forms one of the two guides for the center A , with its horizontal roller r' . The center line of the groove $X X$ represents the direction of e . The groove is cut in the drafting board or the table on which the whole device is mounted. The distance is measured from O to one of the edges of the protractor and a correction is made for its radius.

When it is desired to investigate the performance of a machine at a constant armature current, the set-screw j is tightened, thus fixing the length $A C$. To test the performance of the machine at a constant terminal voltage, the set-screw j' is tightened. To find the characteristics at a constant power factor the set-screw j'' is fastened.

VI. THE LOAD DEVICE

The electrical output of a generator, per phase, is equal to the terminal voltage OA (Fig. 9) multiplied by the component CC' of the current AC . It must be remembered that in the Blondelion the current vector is turned by 90 deg. with respect to its true phase position, so that CC' is the energy component of the current, in phase with the voltage OA . For any setting of the device, the distance from point C to the center XX of the groove can be readily measured and thus the output computed. The same applies to the electrical input of a synchronous motor.

In some uses of the Blondelion it may be desirable to read the electric power directly, on a suitable scale, and for this purpose the arrangement shown in Fig. 9 has been devised. It consists of the articulated parallelogram $uvwR$ and of a celluloid sector RR' , of

shown in the detail sketch in Fig. 8. The sector RR' is forced to remain in contact with the side of the bar OT by means of the tension spring h' shown between the bars uv and wR . With changes in the setting, the sector rolls on OC . The power scale depends upon the radius r of the sector.

The theory of this linkage is as follows: The power, being equal to $OA \times CC'$, is proportional to the area of the triangle OAC . But the same area is equal to $OC \times AA'$, where AA' is the altitude of the triangle with respect to the base OC . Since uv is always parallel to Rw , the triangles OAL and ORC are similar to each other, so that $OC/r = OL/AA'$. Hence,

$$\begin{aligned} \text{Power} &= k_v k_i OA \times CC' = k_v k_i OC \times AA' \\ &= k_v k_i \cdot r \cdot OL \end{aligned}$$

In this expression k_v is the voltage scale coefficient, that is, volts (or kilovolts) per cm.; k_i is the scale

FIG. 8—THE PROTRACTOR AND THE SCALE BAR AC

radius r . The parallelogram is constrained as follows: At R there is a vertical pin with a horizontal roller which can move along the groove XX . The construction is similar to that of the ball bearing guide at A , shown in the detail sketch in Fig. 8. The bar uv has a slot which forces the center line of uv always to pass through point A (Fig. 8). The bar wR can slide through a guide at C . It is proved below that with any setting of the device the power is proportional to the length OL on the main bar OT .

If it is desired to investigate the performance of a generator at a constant output (or that of a motor at a constant input) the double slide at L is fastened to the bar OT by means of the set screw z . This causes the length OL to remain constant, but does not otherwise hamper the motion of the parallelogram, since the two slides at L can turn with respect to each other. The construction is similar to the double slide at point C ,

coefficient of the armature current, that is, amperes per cm. Both coefficients are constant, and so is the radius r , with a given sector. Hence, the power is proportional to the length OL .

As an example, let the Blondelion be set for a three-phase, Y-connected alternator, the current scale being $k_i = 50$ amp./cm., and the e. m. f. scale $k_v = 100$ volt/cm., the voltage being measured per phase of Y . Let the radius of the sector be $r = 25$ cm. To find the power scale, we compute the length OL corresponding to an output of say 1000 kw. per phase. We have

$$1000 \times 1000 = 100 \times 50 \times 25 \times OL,$$

from which $OL = 8$ cm. Hence, the power scale is $1000/8 = 125$ kw. per cm. The scale for the total power for the three phases is 375 kw. per cm.

It is convenient to have several sectors of different radii (Fig. 2) since each sector gives the best results only within a certain range of settings.

In an article on "Hunting and Parallel Operation of Synchronous Machines," *Sibley Journal of Engineering*, March 1920, the author has outlined a method of computation of the synchronizing force, taking into account the no-load saturation curve of the machine. The treatment is based on Blondel's theory of two armature reactions, and in the first approximation the no-load saturation curve is replaced by two straight lines at an angle. Even then the expression for the power trans-

generator and as a motor, and the agreement in all cases has been found satisfactory.

The test curves on the two machines and the other data quoted below were kindly furnished to the author by the engineers of the Westinghouse Electric and Manufacturing Co., and of the Allis-Chalmers Co., to whom he wishes to express his sincere gratitude. The principal data are as follows:

Make	Westinghouse	Allis-Chalmers
Rating as synchronous motor, H. P.....	2800	500
No. of phases.....	3	3
Frequency in cycles.....	60	60
Rated voltage.....	2300	2200
Amperes per phase.....	607	105
Rated at a power factor of.....	0.90	1.00
Speed, rev. per min.....	514	450
No. of poles.....	14	16
Stator connection.....	Y Y	Y
Slots per pole per phase.....	3	3
Coil lies in slots.....	1 and 8	1 and 8
Conductors per slot.....	6	6
Armature I^2R in kw.....	9.9 (at 75° C)	4.1
Field turns per pole.....	68.5	83.5

First of all, the saturation device was set to represent the no-load saturation curve of the Westinghouse machine shown in Fig. 10. The point n , defined in Fig. 5, corresponds in this case to a field current of 100 amperes and to a terminal voltage of 2300. The saturation device was set accordingly for the lengths

FIG. 10—NO-LOAD AND LOAD SATURATION CURVES OF A WESTINGHOUSE SYNCHRONOUS MACHINE OPERATING AS A GENERATOR

mitted electromagnetically between the field pole structure and the armature, as a function of the angle θ , is quite involved. The derivative of this power with respect to θ by definition is the synchronizing power, and its expression is also rather complicated. In the Blondelion the increase in the power OL , for a certain small variation of the angle θ , can be read directly, and the synchronizing force, $\Delta OL / \Delta \theta$, easily computed. Thus, the device should prove useful in fly-wheel computations and in problems on hunting of synchronous machinery.

F. NUMERICAL EXAMPLES AND COMPARISON WITH EXPERIMENTAL DATA

Complete performance characteristics of two actual machines have been obtained by means of the Blondelion and the results compared with the available experimental data on the same machines. In Figs. 10 to 13, the curves represent the actual test results, while the crosses are the readings taken on the Blondelion. The no-load saturation curves (Figs. 10 and 12) were read on the Blondelion with both an increasing and a decreasing voltage, and a slight discrepancy between the two is due to some lost motion in the device. Load curves were checked for each machine working both as a

FIG. 11—THE SHORT-CIRCUIT CURVE AND THE V-CURVES OF A WESTINGHOUSE SYNCHRONOUS MOTOR

100 amperes = 18 cm. and 2300 volts = 45 cm., on the straight part of the saturation curve. The curved plates were then adjusted to give the upper part of the no-load characteristics. It will be noted that the "delta" or terminal voltage was used, and not the Y-voltage; all other voltage vectors in the Blondelion were set in terms of this voltage.

The next step was to estimate the direct armature

stant and equal to 2300 volts. The saturation device and the load device then automatically assumed their proper positions. The set-screw z at L (Figs. 2 and 9) was then tightened to keep the power input into the machine constant. The field current was read.

After this, the bar AC was turned stepwise, by a few degrees at a time, and the new field and armature currents were read at each step. This was done for a lagging and a leading current and the points so obtained were marked by crosses on the full-load V -curve shown in Fig. 11. The length OL was then reduced to one half, and similar points were obtained, shown on the half-load V -curve. Subsequently the V -curves at $1\frac{1}{2}$, 2 and $2\frac{1}{2}$ times full load were checked, by setting OL equal to that many times its length at the rated load. The no-load V -curve was checked by making $OL = O$. The curve which connects the lowest points of the V -curves, that is, the unity power factor curve, was checked by setting the screw j' so as to keep the

power factor at 100 per cent, and varying the field current and the armature current. The load device was not used in this last test.

The curves of the Allis-Chalmers machine, shown in Figs. 12 and 13, were checked in a similar manner, and it would be a needless repetition to quote here the numerical data. It must be stated, however, that no actual load tests were made on this machine running as a generator. The maker of the machine stated to the author that the curves in Fig. 12 at 90 and at 100 per cent power factor were computed by the A. I. E. E. method and that the point f was estimated from tests on similar machines.

The writer's assistant, Mr. O. K. Marti, actually built the device and performed all the measurements described above. To him credit is also due for several mechanical details and for the drawings used in this paper. The author wishes to express to him his sincere appreciation of the valuable assistance rendered.

magnitude but rotates with an angular velocity of ω . In the fourth and general case (d) the magnitude of the vector diminishes exponentially while it rotates at a constant angular velocity of ω . Thus the general form of transient current may be represented by a vector which rotates at a constant angular velocity and whose terminus travels along a logarithmic spiral.

The velocity of the terminus of the vector has two components, one along the vector and one perpendicular to it. It is convenient to measure these component velocities in multiples of the instantaneous length of the vector. The term angular velocity is thus appropriate. This is a broader meaning of angular velocity than is ordinarily assigned to it, and for this reason, it is spoken of as the generalized angular velocity. Differentiation shows that the generalized angular velocity of this vector is, $m = (-\alpha + j\omega)$. See Fig. 2. Notice that the usual significance is attached to the symbol j . It indicates that the vector $j\omega$, lags the vector, $-\alpha$, by 90 degrees.

FIG. 1—THE END OF EACH VECTOR WHICH IS DRAWN FROM THE ORIGIN IS INDICATED BY A LARGE PERIOD; THE END OF SMALL VECTORS DRAWN FROM THESE PERIODS IS INDICATED BY ARROWHEADS.

The form of the current variation is determined by the generalized angular velocity; the magnitude is determined by the coefficient I , and the phase, by the angle, θ .

It is interesting to note that the current is passing through a maximum value at the moment that the current vector makes an angle $\arctan \alpha/\omega$ with the projection axis. This occurs when the vector is in such a position that the angular velocity m , drawn from its terminus, is perpendicular to the projection axis. See Fig. 3. A steady sinusoidal current is maximum at the moment that the vector representing it lies in the projection axis.

The behavior of damped sinusoidal currents in electric circuits, having resistance inductance and capacitance, has been the subject of considerable investigation, and is familiar, especially to those who have been interested in radio communication. The field of application of this theory, however, is much broader than this, and may easily be extended to include

practically all electric machinery, both alternating and direct-current.

Currents and pressures that have the same generalized angular velocity can, of course, be combined by the customary principles of vector addition. The resulting vector diagrams will then be similar to those which apply to the steady state, save that the electromotive forces due to induction, both self and mutual, are not in time quadrature with the current, as we shall presently see. It is further understood that, as they rotate, all of the vectors shrink exponentially.

FIG. 2

FIG. 3

Inasmuch as those who are interested in the operation of electric machinery have had little contact with the theory of damped sinusoidal currents, it may be well to show how these currents and the electric pressures they produce can be represented by vectors. In all of the following analyses any capacitance that the circuit may possess will be disregarded. This, of course, places a definite limitation upon the scope of the analysis and prevents the discussion of certain transient conditions, particularly those of relatively high frequency, which are very important in transmission circuits.

FIG. 4

When a current of the general form flows through a non-reactive resistance the fall in potential is $r I e^{-\alpha t} \sin(\omega t + \theta)$. This may be represented vectorially as in Fig. 4. The fall in potential through an inductance is:

$$L \frac{di}{dt} = -\alpha L I e^{-\alpha t} \sin(\omega t + \theta) + \omega L I e^{-\alpha t} \cos(\omega t + \theta)$$

The first of these components may be represented by a vector in opposition to the current vector, and the second by a vector which leads the current by 90 degrees.

See Fig. 4. In this figure and hereafter a line drawn above a letter indicates that it represents a current or pressure of the general form.

$$\text{Thus: } \bar{V} = r \bar{I} + (-\alpha + j\omega) L \bar{I}$$

$$\text{or } \bar{V} = (r + m L) \bar{I}$$

where m represents the generalized angular velocity of the current vector; the generalized impedance is $(r + m L)$.

In Fig. 4 notice that there is a rise in potential through the circuit, numerically equal to $\alpha L I$, which is in time phase with the current. This indicates that electric energy is being generated within the circuit, due to the diminution of the magnetic field. The power so generated, $\alpha L I^2$, partially supplies the copper loss, $I^2 r$, in the circuit. The vector representing the fall in pressure due to self inductance leads the vector representing the current by arc $\tan \alpha/\omega$ more than 90 deg. It is in this respect that the vector diagrams representing the transient state differ from those that represent the steady state.

If the electric circuit is linked with a magnetic circuit in which eddy current and hysteresis losses may occur, it is customary, though strictly speaking it is incorrect, to represent both the current and the magnetic flux by vectors when they have a steady sinusoidal variation.

FIG. 5

FIG. 6

In this case the flux is represented as lagging the current which produces it by a constant angle β . See Fig. 5. This is equivalent to assuming that the hysteresis loop is an ellipse and that the eddy currents are all in time quadrature with the flux in the core. The fall in reactive pressure $j\omega L I$, leads the flux, ϕ , by 90 deg., but the current by an angle which is somewhat less. This being the case, it is necessary to represent the inductance by a complex number, i. e. $L = L_1 - j L_2$; where $L_2/L_1 = \tan \beta$. Thus $j\omega L I = j\omega (L_1 - j L_2) I = \omega L_2 I + j\omega L_1 I$.

Similarly if the current is of the general form,—and we make the same assumption in regard to the constancy of the phase angle between the flux and the current,—the fall in pressure due to inductance is $(-\alpha + j\omega) (L_1 - j L_2) \bar{I}$, which may still be written $m L \bar{I}$, understanding now that both m and L are complex numbers. On expansion, this becomes $[(-\alpha L_1 + \omega L_2) + j(\omega L_1 + \alpha L_2)] \bar{I}$. If αL_1 equals ωL_2 , i. e. if $\alpha/\omega = \tan \beta$, the fall in pressure due to inductance is in exact quadrature with the current and the energy given up

by the magnetic field due to its collapse is just sufficient to supply the core losses. The power absorbed in the coil is then equal to the copper loss. If, with the same frequency, the rate of collapse of the magnetic field is greater than this, the coil absorbs less power than the copper loss.

If there is another electric circuit linking the same magnetic core, the fall in electric pressure through it produced by the action of the current in the first circuit is $j\omega M \bar{I}_1$. Notice that this is a vector which leads the current vector by more than 90 deg. When there are core losses in the mutual magnetic circuit the mutual inductance, M_1 , might likewise be represented by a complex number of the form, $M_1 - j M_2$.

Only considerable research can determine the value of this suggestion that the self and mutual inductance be represented by complex numbers when the currents are decaying sinusoids. It should be noted that there is a constant lag angle of flux with respect to magnetizing current only if the hysteresis "loop" is a diminishing ellipse such as shown in Fig. 6. This is, of course, not true and whether it is justifiable can only be determined by experiment.

In any inductive circuit the current cannot immediately respond to an abrupt change in the magnitude or form of the applied electromotive forces. There is always a transient condition of current flow, the duration of which is determined by the inductance and resistance of the circuit. Moreover, the form of this transient flow is determined solely by these constants and is wholly independent of the character of the applied electromotive forces. The magnitude and phase of the transient, however, are determined by the initial and final values of the current in the circuit, and these are fixed by the applied electromotive forces.

TWO CIRCUITS HAVING MUTUAL INDUCTANCE BUT NO MOTION WITH RESPECT TO EACH OTHER

The simplest case we shall consider is that of a single-phase transformer which is simultaneously short-circuited on both primary and secondary sides.

With the primary winding short-circuited the fall in pressure through it is zero.

$$\bar{I}_1 r_1 + \bar{I}_1 m L_1 + \bar{I}_2 m M = 0 \quad (1)$$

r_1 and L_1 represent the resistance and self inductance, not leakage inductance, of the primary. M is the mutual inductance between primary and secondary. Likewise:

$$\bar{I}_2 r_2 + \bar{I}_2 m L_2 + \bar{I}_1 m M = 0 \quad (2)$$

The primary and secondary currents have the same form and thus the same generalized angular velocity. Eliminating $\bar{I}_1$ and $\bar{I}_2$ from equations (1) and (2) gives:

$$(r_1 + m L_1) (r_2 + m L_2) = m^2 M^2$$

$$\text{Expand and divide each term by } L_1 L_2 \text{ giving,}$$

$$\sigma m^2 + (k_1 + k_2) m + k_1 k_2 = 0 \quad (3)$$

$$\text{where } \sigma = 1 - \frac{M^2}{L_1 L_2} \quad k_1 = r_1/L_1 \text{ and } k_2 = r_2/L_2$$

By some writers σ is called the leakage coefficient, whereas others define the leakage coefficient as

$$\frac{L_1 L_2}{M^2} - 1. \text{ In the latter case } \left(\frac{L_1 L_2}{M^2} - 1 \right) = \sigma' =$$

$$\frac{\sigma}{1 - \sigma}; \text{ or } \sigma = \frac{\sigma'}{1 + \sigma'}. \text{ In a transformer in which}$$

the resistance of the windings may be neglected this leakage coefficient, σ , is the ratio of the current on open circuit to that on short circuit with the same applied potential. k_1 and k_2 are the reciprocals of the time constants of the two windings on open circuit.

The solution for the generalized angular velocity is

$$m = -\frac{k_1 + k_2}{2\sigma} \pm \frac{\sqrt{(k_1 + k_2)^2 - 4\sigma k_1 k_2}}{2\sigma} \quad (4)$$

Since σ is less than unity, the values of m are both real, and the transient current consists of two direct-current components one of which diminishes much faster than the other. These currents may be represented by vectors as in Fig. 1B.

In this case, in which both windings are short-circuited, there will be no current in either winding after the transient has disappeared. Thus the only current after short-circuit occurs is the transient. Let the vectors I_{10} and I_{20} represent the primary and secondary currents before short circuit occurs. Also let $\bar{I}_1'$ and $\bar{I}_1''$ represent the components of the transient current in the primary and similarly for the secondary. Then at the moment of short circuit, the sum of the instantaneous values of the two transient components must equal the instantaneous value of the initial current in both primary and secondary. The transient components might thus be represented by an indefinitely great number of vectors since it is only necessary that their projection on the given axis have specified values. It is more convenient, however, if they are chosen so that their vector sum is equal to the vector representing the initial current before short circuit. Thus we will write:

$$I_{10} = \bar{I}_1' + \bar{I}_1'' \quad (5)$$

$$\text{and} \quad I_{20} = \bar{I}_2' + \bar{I}_2'' \quad (6)$$

Remember that the vectors $\bar{I}_1'$, etc., are diminishing exponentially and that this equality holds only at the moment of short circuit. Further, notice that the vectors I_{10} and I_{20} are drawn to represent the *maximum* values of the currents before short circuit. Each of these transient components must satisfy equations (1) and (2). Substitute in equation (1) and write in the following form:

$$\bar{I}_1' \frac{(r_1 + m' L_1)}{m' M} = -\bar{I}_2'$$

$$\text{also} \quad \bar{I}_1'' \frac{(r_1 + m'' L_1)}{m'' M} = -\bar{I}_2''$$

where m' and m'' are the two values of m as indicated by equation (4). If these equations are added and $(I_{10} - \bar{I}_1')$ is substituted for $\bar{I}_1''$ the solution for $\bar{I}_1'$ is:

$$I_1' = \frac{m' m''}{k_1 (m' - m'')} \{ (k_1/m'' + 1) I_{10} + \sqrt{1 - \sigma} \sqrt{L_2/L_1} I_{20} \} \quad (7)$$

$$\text{also } I_1'' = \frac{m' m''}{k_1 (m'' - m')} \{ (k_1/m' + 1) I_{10} + \sqrt{1 - \sigma} \sqrt{L_2/L_1} I_{20} \} \quad (8)$$

The product of the two roots divided by their difference is

$$\frac{m' m''}{m' - m''} = \frac{k_1 k_2}{\sqrt{(k_1 + k_2)^2 - 4\sigma k_1 k_2}}$$

In a transformer the ratio of the self-inductances of the primary and secondary is practically equal to the square of the ratio of the turns. Thus as is commonly said, $\sqrt{L_2/L_1} I_{20}$ is the secondary current referred to the primary. In order to reduce these expressions to a more understandable form, we will assume that k_1 equals k_2 . This is very nearly true. If this is done the two components of the primary current become:

$$\bar{I}_1' = 1/2 (I_{10} + I_{20}) \quad (9)$$

$$\bar{I}_1'' = 1/2 (I_{10} - I_{20}) \quad (10)$$

where I_{20} is now the secondary current referred to the primary. The values of m reduce to:

$$m' = -\frac{r}{L + M}$$

$$m'' = -\frac{r}{L - M}$$

where r and L are the resistance and self-inductance of the primary winding, and M is the mutual inductance on the assumption that both windings have the same number of turns. In this case the difference of the self and mutual inductances is the leakage inductance of one winding. The two components of the transient secondary current are similar to those of the primary. Thus at the moment of short circuit each of the currents in the two windings breaks up into two components, one of which is one-half of the no-load current; $(I_{10} + I_{20})$ is the no-load current. This component decays at a rate determined by the resistance and the sum of the self and mutual inductances of the two windings. It is due to the energy stored in the magnetic core of the transformer. Its rate of decay is much slower than that of the other component. The latter's rate of decay is determined by the resistance and leakage inductance of the windings, and this component of the currents is due to the energy stored in the leakage field. The vector diagram and oscillograph record are given in Fig. 7. In this figure the vectors I_1 and I_2 , representing the primary and secondary currents,

are rotating at an angular velocity of ω . At the moment of short circuit each of these vectors abruptly stops and breaks up into two component vectors which diminish at different rates.

The more usual transient condition would be one in which the short circuit occurred on the secondary side alone. In this case the current immediately after short circuit consists of the transient current together with the steady value of the short-circuit current. The conditions that must be satisfied are now:

$$I_{10} = \bar{I}_1' + \bar{I}_1'' + I_{sc1} \quad (11)$$

$$\text{and} \quad I_{20} = \bar{I}_2' + \bar{I}_2'' + I_{sc2} \quad (12)$$

FIG. 7

where I_{sc1} and I_{sc2} represent the steady values of the short-circuit currents in the primary and secondary windings. As before this is a vector equation which holds only at the moment of short circuit. If these steady short-circuit currents are transferred to the left of the equality sign it is readily seen that the values of the components of the transient currents become:

$$I_1' = 1/2 (I_{10} + I_{20}) - 1/2 (I_{sc1} + I_{sc2}) \quad (13)$$

$$I_1'' = 1/2 (I_{10} - I_{20}) - 1/2 (I_{sc1} - I_{sc2}) \quad (14)$$

As before the secondary components are similar to the primary components. It is now necessary to determine the phase relation between the steady short-circuit current and the current in the transformer before the short circuit occurs.

In order to keep the diagrams as simple as possible, we will make the customary assumption that the primary and secondary currents are equal and in phase opposition. In that case the first component of the transient current is zero, and the second component is equal to the current before short circuit minus the steady short-circuit current. [See equations (13) and (14)] with $I_{10} = -I_{20}$ and $I_{sc1} = -I_{sc2}$. The error thus introduced is usually very slight. The vector diagram at the moment of short circuit is given in Fig. 8.

Before short circuit occurs only the four vectors representing the primary and secondary potentials and current appear. They are rotating at a uniform angular velocity, ω . At the instant after short circuit

all of these except the primary potential disappear and in their place spring the steady short-circuit currents. I_{sc1} and I_{sc2} and the transient currents I_1'' and I_2'' . The former continue to rotate at an angular velocity of ω without change in magnitude, while the latter remain fixed in angular position but diminish exponentially at a rate, α , depending upon the resistance and leakage inductance of the windings. The arrows at the ends of the vectors indicate the direction of their motion. Observe that, at the moment of short circuit, the current before short circuit is the vector sum of the steady short-circuit current and the transient current. Since the steady short-circuit current is from 10 to 25 times the full-load current, it makes little difference whether the short circuit comes at a time of full load or no load. It may be a little more severe at no load. On account of the excessive value of the steady short-circuit current, the vectors representing it and the transient current are essentially in phase opposition at the moment of short circuit. Half a cycle after short circuit occurs the vector I_{sc1} will thus have overtaken the stationary vector I_1'' and their vector sum will be a maximum. It at once follows that short circuit is most severe when it occurs at a moment that the steady short-circuit current would be a maximum.² Since the steady short-circuit current and applied potential are nearly in quadrature, for example, the power factor of a certain 1000-kv-a., 60-cycle transformer is 0.15 at short circuit,—the worst moment for a short circuit to occur is at about the time

FIG. 8

that the applied potential is passing through zero. In the transformer just cited the ratio of the resistance to the leakage inductance is 56 and thus in the time of one half cycle the transient current will have fallen to $e^{-\frac{56}{120}}$ or 63 per cent of its initial value. Thus the first current rush would be to a value which is 63 per cent greater than the maximum value of the steady short-circuit current which is itself more than 20 times the maximum value of the full-load current. The

2. To determine the exact moment at which the short-circuit current would be a maximum involves the solution of a mixed trigonometric and exponential equation, which is decidedly not worth while in the present problem.

forces between turns vary as the square of the current, and thus the first shock on this transformer may be 265 per cent of its ultimate maximum value.

When these forces have their maximum value they occur one-one-hundred-and-twentieth ($1/120$) of a second after short circuit in a sixty-cycle transformer and one-fiftieth ($1/50$) of a second after short-circuit in a twenty-five-cycle transformer. Nevertheless with transformers having the same short-circuit characteristics (volts, amperes, and watts on short-circuit test), the maximum forces that the windings must sustain are the same for all frequencies.

If the transformer is but a portion of the electric circuit in which the transient takes place the characteristic equations (1) and (2) must be written:

$$\bar{I}_1 r_1 + \bar{I}_1 m L_1 + \bar{I}_2 m M = \bar{V}_1 \quad (15)$$

$$\bar{I}_2 r_2 + \bar{I}_2 m L_2 + \bar{I}_1 m M = \bar{V}_2 \quad (16)$$

$\bar{V}_1$ and $\bar{V}_2$ are the transient potentials which appear at the terminals of the transformer. If the transformer has a relatively small exciting current little error will be made if it is treated like a simple inductive reactance. In this case the relation between the primary and secondary pressures is much simpler.

$$\bar{V}_1 - \bar{I}_1 (R + m L) = a \bar{V}_2 \quad (17)$$

R and L are the equivalent resistance and leakage inductance of the two windings and a is the ratio of transformation at no load.

TWO CIRCUITS HAVING MUTUAL INDUCTANCE, IN ONE OF WHICH THERE IS A COMMUTATED ROTATIONAL E. M. F.

Before turning our attention to polyphase rotating machines, it might be well to consider briefly the direct-current dynamo of either the shunt or compound type. This apparatus is in some respects quite similar to the transformer. It has two circuits which are mutually inductive, the armature and series field forming one and the shunt field the other. There is this difference, however: an electromotive force is generated in the armature circuit by its rotation in a magnetic field that is due to the joint action of the current in both circuits. With constant speed this generated e. m. f., is proportional to the magnetic field. The relation between the magnetic field and the currents in the armature and shunt field circuits which produce it is similar to the well-known hysteresis loop, for which there is no simple mathematical expression. In some problems in which the exciting current is a steady alternating one, it has been found convenient, however, to assume that this hysteresis loop is an ellipse. If this assumption should prove sufficiently accurate in the present case also, it will simplify the problem greatly, for as has been already suggested, we may then represent the magnetic field and the rotational e. m. f. which it produces, together with the net exciting ampere-turns by vectors even when these quantities are damped sinusoids, *i. e.*,

of the general form. This vector relation is shown in Fig. 9, which is drawn for the steady state.

The flux, ϕ , and the rotational e. m. f. E which is proportional to it, lag the exciting current I by a constant angle β . Thus we may write

$$E = (K_1 - j K_2) I \quad (18)$$

$$\text{or } E = K I$$

where K is a complex number, $K_1 - j K_2$, having the dimensions of resistance. The vector equation shows that when the instantaneous value of the current is zero

FIG. 9

FIG. 10

the generated e. m. f. is $K_2 I$. This is generally referred to as the residual voltage. At the moment that the current has its greatest value the rotational e. m. f. is $K_1 I$. If the exciting current is going through a steady cyclic variation, it is a simple matter to determine these two components of the e. m. f. See Fig. 10. When the current is a damped sinusoid, however, the vector representing it is shorter at the moment that it is perpendicular to the time axis than it was earlier in the cycle when the current was passing through

FIG. 11

its maximum value. See Fig. 11. In this case the best method of determining the constants K_1 and K_2 , in order to assure the greatest accuracy in the calculations can only be determined by experiment.

Let $\bar{I}_1$ and $\bar{I}_2$ be the currents in the armature and shunt field circuits and similarly, r_1 and L_1 , the resistance and self-induction of the one, and r_2 and L_2 , the same constants of the other. Also let M be the mutual inductance between the two circuits. The e. m. f., $\bar{E}$, generated in the armature circuit by rotation is:

$$\bar{E} = K (N_1/N_2 \bar{I}_1 + \bar{I}_2);$$

where N_1 and N_2 are the effective turns in each circuit

acting on the main magnetic axis. Let $N_1/N_2 = a$. Also let $\bar{V}$ be the rise in terminal pressure across both the armature and shunt field circuits.

Then we have:

$$\begin{aligned}\bar{V} &= \bar{E} - \bar{I}_1 r_1 - \bar{I}_1 m L_1 - \bar{I}_2 m M \\ &\quad \text{(armature circuit)} \\ &= \bar{I}_1 (K a - r_1 - m L_1) + \bar{I}_2 (K - m M) \quad (19)\end{aligned}$$

$$\begin{aligned}\text{also } \bar{V} &= -\bar{I}_2 r_2 - \bar{I}_2 m L_2 - \bar{I}_1 m M \\ &\quad \text{(shunt field circuit)} \\ &= -\bar{I}_2 (r_2 + m L_2) - \bar{I}_1 m M \quad (20)\end{aligned}$$

If these equations, (19) and (20), are solved for $\bar{I}_1$ and $\bar{I}_2$ we have:

$$\bar{I}_1 = \frac{r_2 + m L_2 + K - m M}{(K a - r_1 - m L_1)(r_2 + m L_2) - (K - m M)m M} \bar{V}$$

$$\text{and } \bar{I}_2 = \frac{K a - r_1 - m L_1 + m M}{(K a - r_1 - m L_1)(r_2 + m L_2) - (K - m M)m M} \bar{V}$$

The total net current delivered, $\bar{I} = \bar{I}_1 + \bar{I}_2$, is

$$\bar{I} = \frac{r_1 + r_2 + K(1 - a) + m(L_1 + L_2 - 2M)}{(K a - r_1 - m L_1)(r_2 + m L_2) - (K - m M)m M} \bar{V}$$

The ratio of the fall in terminal potential, $-\bar{V}$, to the total current is the generalized impedance, Z , of the dynamo. Thus we have:

$$Z = \frac{(K - m M)m M - (K a - r_1 - m L_1)(r_2 + m L_2)}{r_1 + r_2 + K(1 - a) + m(L_1 + L_2 - 2M)}$$

For further discussion of this problem the reader is referred to the paper by Doherty on "Exciter Instability" presented at the Pacific Coast Convention, August, 1922.

TWO SYSTEMS OF BALANCED POLYPHASE CIRCUITS HAVING A CONSTANT RELATIVE ANGULAR VELOCITY

The author believes that the simplest method of presenting the analysis of the transient condition in polyphase induction and synchronous machines is that which considers the rotating magnetic fields in the air gap and the reactions which they produce. When these polyphase machines are operating under balanced conditions, either steady or transient, the currents in the several phases of the polyphase winding may be represented by vectors of equal length equally spaced with respect to each other. For the steady condition the vectors are of constant length and rotate at a constant angular velocity. This representation has been used for many years. The *only* difference between the steady and the transient condition is that the vectors which represent the latter state diminish exponentially as they rotate. If this conception of the transient state is borne in mind the following analysis is readily

followed by anyone who is familiar with the steady operation of these machines. In all that follows the relative speed of the two windings is assumed to remain constant throughout the time considered. Since the maximum current occurs within about a half-cycle after the transient begins the angular velocity of the moving part has little opportunity to change before the first shock is over.

The parallel lines in Fig. 12 represent the uniform air gap of a three-phase induction motor. The phase belts of the stator conductors are indicated at the letters a, b, c . The pole pitch is from $+a$ to $-a$. If this winding is properly designed, there will be very small harmonics in the space distribution of the air-gap flux density when the alternating currents are balanced. We will neglect whatever harmonics may exist and assume that this distribution may be represented by a sinusoidal curve such as β . The line $X-X$ is the axis of this curve. If the current in phase b lags that in phase a by 120 deg. this magnetic field will move toward the right at a constant angular velocity of ω radians per second; where ω equals the frequency of the alternating current multiplied by 2π . On the other hand, if the current in phase b leads that in phase

a the field moves toward the left at the same velocity. In all that follows we shall consider that a velocity toward the right is positive and that one toward the left is negative. Furthermore, the magnitude of the field as well as its form, will not change as it moves, and thus the field might be represented by a rotating vector whose projection on a fixed axis indicates the amount of flux linking any particular phase. The angular displacement of this vector from the fixed axis is always the angle between the axis of the moving field and the axis of the phase considered. See Fig. 13. One of the most important points in the theory of rotating fields that are produced in this manner in a uniform air gap is that the flux through any phase is a maximum at the moment that the current in that phase is also a maximum. For example, when the current in phase a is maximum the field is in the position β_a . One sixth of a cycle later, the current in $-c$ will be a maximum and in the same time interval, the flux distribution will have moved one sixth of two full pole pitches toward the right and be a maximum through this phase, $-c$. In a similar manner, it will have moved into the position β_b by the time that the current in phase b is a maximum. This can be represented vectorially as in Fig. 13. The current and flux are

represented by the rotating vectors I and ϕ . The instantaneous value of the current in any phase or the flux through that phase is the projection of the corresponding vector on the axis of that phase. In Fig. 13 the vectors are drawn for the time that the current in phase c has its maximum value. Notice that for both the phases a and b the currents in them and the fluxes through them are each one half of their maximum values. There is this difference, however, for while the values are decreasing for phase a they are increasing for phase b , in which they will be a maximum $1/6$ of a cycle later. Ordinarily, we are content to know the current and flux in any one phase, a , for example, and then the projection axes for the other phases are not drawn.

FIG. 13

It may be convenient and possibly necessary in some problems to consider magnetic fields that rotate to the left, that is, with a negative angular velocity. In this case the vector, ϕ , representing the flux through any phase would likewise have a negative angular velocity and would thus move in the clockwise direction. If the trigonometric expressions for the instantaneous currents in the phases are written it will be noticed that giving a negative value to ω is equivalent to reversing the phase order of the currents. Such a reversal of phase order reverses the direction of rotation of the magnetic field produced by the current. If the current vector in Fig. 13 is rotated in the negative or clockwise direction it will be noticed that the current in phase b will lead that in phase a by one-third of a cycle, that is the phase order of the currents is reversed. We must be most careful, however, to remember that, if it is necessary to combine or operate on these vectors, whether they have positive or negative angular velocities the operator j always indicates a phase rotation of one quadrant in the positive or counter clockwise direction. If this is not done we may become hopelessly confused. If the air gap is not uniform, as is the case with salient pole machines, the curve of flux density will alter both its shape and magnitude as it rotates, but that is a complication which it is well for the present to disregard, leaving its consideration until some future time.

In general if the currents in the several phases of

a symmetrical n -phase winding have values equal to the projections of a "current" vector on each of a system of n equally spaced axes, the magnetic flux linking any winding is equal to the projection of a "flux" vector, which is drawn in phase with the "current" vector, on the axis corresponding to that winding. This assumes that the windings are so designed that there are essentially no harmonics in the space distribution of the magnetic field and that each winding will, if acting alone, produce exactly the same flux per ampere.

If the currents are of the general form both the "current" and "flux" vectors shrink exponentially as they rotate. The space distribution of the magnetic field is still sinusoidal at all times but its magnitude diminishes as it moves through the air gap. Compare Fig. 13 with Fig. 14. In the latter figure let us assume that the currents took on the general form at the moment that the flux distribution was at the point indicated by the curve β , and that their generalized angular velocity is $(-\alpha + j\omega)$. The equation of the maximum density for any later position of the field such as β_1 is: $B_m = B_0 e^{-\alpha t}$; where t is the time required for the field to move from the position β to β_1 , i. e., through an angular distance X .

The flux through any phase as well as the current in it may still be represented by a vector although this vector is now of the general type—that is, it shrinks exponentially as it rotates. A current or flux variation of the general form reaches its maximum value in any phase at the moment that the vector which represents it is still arc $\tan \alpha/\omega$ from the projection axis of this phase. Because the field is shrinking as it rotates the flux linking phase a is greater when the field is in the position β_1 than when it is in the position β_2 at which moment the axis of the field is coincident

FIG. 14

with the axis of the phase. See Fig. 15. Thus the flux through any phase is a maximum at the moment that the current in the phase is a maximum, but the flux distribution is no longer directly opposite the phase when this occurs, as was the case when the currents were steady sinusoids.

It is then evident that even in the transient state the flux through any phase and the current in that phase may still be represented by coincident vectors.

The electromotive force generated by this rotating field is the negative of the time rate of change of the flux linkages. Thus, in general, when this time rate of flux change in any phase is zero the e. m. f. is zero and the flux linking the phase is a maximum. In Fig.

upon the constants of the b windings and their terminal pressure. In any case, however, the current will be represented by a vector equal to $\frac{\bar{E}_b - \bar{V}_b}{r_b + m L_b}$; where

$\bar{V}_b$ is the terminal pressure, r_b the resistance and L_b the synchronous inductance of one of the b phases. By the time the current in the winding has reached its maximum value the field will have advanced a further relative angle of θ . Thus whether the motion of the a field is positive or negative, its action on the b winding will develop a field which will always lag the a field in its motion with respect to the b winding. Consider an induction machine in which the magnetic field due to the stator, a windings, rotates in the positive direction at ω radians per sec. If the rotor turns in the same direction at less than this synchronous speed the relative motion of the stator field with respect to the rotor is positive. The rotor component of magnetic field actually and apparently lags the stator field. If the rotor turns in the same direction at a speed greater than synchronous, the relative motion of the stator field with respect to the rotor is negative and the rotor component of field apparently leads when observed from the fixed stator, though it actually lags, as would be observed from any point on the rotor itself. It is interesting that these well-known facts should apply to the transient state as well as to the steady operating condition.

Having established these general principles in regard to rotating fields during the transient state the solution for the transient currents in an induction motor may be written down without further explanation. If the generalized angular velocity of the stator currents is m the relative generalized angular velocity of the field produced by these currents with respect to the rotor is $(m - j p)$. Since $m = -\alpha + j \omega$ and the relative angular velocity of the stator magnetic field and the rotor winding is $(\omega - p)$, the generalized angular velocity of the rotor currents is $-\alpha + j(\omega - p)$, i. e., $m - j p$. The generalized angular velocity of the rotor currents is thus $m - j p$, but the relative angular velocity with respect to the stator of the field produced by them is $[m - j p - (-j p)]$, i. e., m . The second $(-j p)$ is the relative angular velocity of the stator with respect to the rotor. Thus we have:

$$\bar{E}_2 = - (m - j p) M \bar{I}_1 \quad (19)$$

$$\bar{E}_1 = - m M \bar{I}_2 \quad (20)$$

$\bar{E}_2$ and $\bar{E}_1$ are respectively the generated e. m. f. due to the stator currents in the rotor and that due to the rotor currents in the stator. The rotor current, $\bar{I}_2$, is:

$$\bar{I}_2 = \bar{E}_2 / Z_2 \quad (21)$$

where Z_2 is the generalized self impedance of the rotor calculated for a generalized angular velocity of $m - j p$. The stator current $\bar{I}_1$, is:

$$\bar{I}_1 = \frac{\bar{E}_1 - \bar{V}_1}{Z_1} \quad (22)$$

where Z_1 is similarly the generalized self impedance of the stator calculated for a generalized angular velocity of m , and $\bar{V}_1$ is the transient terminal pressure of the stator. Combining these four simple relations gives the characteristic equation for the stator current of an inductor motor during the transient period. That is:

$$\begin{aligned} \bar{I}_1 &= - \frac{Z_2}{Z_1 Z_2 - m (m - j p) M^2} \bar{V}_1 \\ &= \frac{-\bar{V}_1}{Z_T} \end{aligned} \quad (23)$$

where $-\bar{V}_1$ is the fall in terminal pressure across one phase of the stator. That is, it may be said that the transient impedance of an induction machine is:

$$Z_T = \frac{Z_1 Z_2 - m (m - j p) M^2}{Z_2} \quad (24)$$

The steady operating impedance is

$$Z_0 = \frac{Z_1 Z_2 - j \omega (j \omega - j p) M^2}{Z_2} \quad (25)$$

where $Z_1 = r_1 + j \omega L_1$ and $Z_2 = r_2 + j (\omega - p) L_2$. If the transient occurs when the stator winding is symmetrically short-circuited or if it occurs when the stator is connected to a circuit whose resistance and inductance are many times smaller than the similar constants of the motor, the transient terminal pressure of the stator is essentially zero. It is thus evident that the transient impedance is also zero. Equating the transient impedance Z_T to zero gives the characteristic equation for an induction motor and determines the generalized angular velocity of the stator current.

Since $Z_1 = r_1 + m L_1$ and $Z_2 = r_2 + (m - j p) L_2$ equating the transient impedance to zero gives $(r_1 + m L_1) [r_2 + (m - j p) L_2] - m (m - j p) M^2 = 0$. Expanding and collecting terms and dividing by $L_1 L_2$ gives the following quadratic in m :

$$\sigma m^2 + (k_1 + k_2 - j p \sigma) m + k_1 k_2 - j p k_1 \quad (26)$$

where $k_1 = r_1 / L_1$, $k_2 = r_2 / L_2$ and $\sigma = 1 - \frac{M^2}{L_1 L_2}$

Notice that this characteristic equation for the induction motor is identical with that for a transformer with the exception of two terms, $-j p \sigma m$, and $-j p k_1$. These terms, however, completely alter the form of the transient. The solution for the generalized angular velocity, m , is:

$$\begin{aligned} m &= - \frac{(k_1 + k_2)}{2 \sigma} + \frac{j p}{2} \\ &\pm \frac{\sqrt{(k_1 + k_2 - j p \sigma)^2 - 4 \sigma (k_1 k_2 - j p k_1)}}{2 \sigma} \end{aligned} \quad (27)$$

If $k_1 = k_2$, the quantity under the radical is real and will be negative unless the equivalent resistance is somewhat greater than the equivalent reactance as measured with the rotor blocked, a most unusual con-

If an induction motor or generator is short-circuited on all phases I_{1s} and I_{2s} are both zero since there will ultimately be no current in the machine. If an induction motor or generator is connected to a line when it carries no current, I_{10} and I_{20} are both zero. We shall work out in detail only the first of these cases since nothing is gained in generality by doing more.

Each of the transient components must satisfy the vector relation:

$$(r_1 + m L_1) \bar{I}_1 + m M \bar{I}_2 = 0$$

and thus we may write:

$$(r_1 + m' L_1) \bar{I}_1' + m' M \bar{I}_2' = 0 \quad (32)$$

$$(r_1 + m'' L_1) \bar{I}_1'' + m'' M \bar{I}_2'' = 0 \quad (33)$$

also at the moment of short circuit

$$\bar{I}_1' + \bar{I}_1'' = I_{10} \quad (34)$$

and

$$\bar{I}_2' + \bar{I}_2'' = I_{20} \quad (35)$$

Solving these four simultaneous equations for the components of the transient currents in the stator winding gives:

$$I_1' = \frac{m' m''}{m' - m''} [M/r_1 I_{20} + (1/k_1 + 1/m'') I_{10}]$$

$$\text{and } \bar{I}_1'' = \frac{m' m''}{m'' - m'} [M/r_1 I_{20} + (1/k_1 + 1/m') I_{10}]$$

These expressions are readily reduced to understandable forms if suitable approximations are made. If $k_1 = k_2 = k$ the values of m' and m'' are approximately

$$m' = -k/\sigma + j p \quad (36)$$

$$m'' = -k/\sigma + j 0 \quad (37)$$

Also

$$M = \sqrt{1 - \sigma} L$$

$$= (1 - \sigma/2) L \quad \text{approximately}$$

where L is the synchronous self inductance of either the stator or rotor winding. The approximate values of the transient components become:

$$I_1' = I_{10}/2 - 1/\sigma I_n$$

$$I_1'' = I_{10}/2 + 1/\sigma I_n$$

The error in these values is well within 10 per cent ordinarily. Notice that the transient currents depend almost entirely upon the no-load current, I_n , and the leakage coefficient, σ . It makes little difference

4. More exact solutions for the component currents, based on the approximate values of m are:

$$\bar{I}_1' = \left(1 + j \frac{k}{\sigma p}\right) \left(I_{10}/2 - \frac{\sqrt{1 - \sigma}}{\sigma} I_n\right)$$

$$\text{and } \bar{I}_1'' = \left(1 + j \frac{k}{\sigma p}\right) \left(\frac{1 - j \frac{k}{\sigma p}}{1 + j \frac{k}{\sigma p}} I_{10}/2 + \frac{\sqrt{1 - \sigma}}{\sigma} I_n\right)$$

whether short-circuit occurs at no-load or full load. The first of these components rotates at approximately synchronous speed while the second is practically stationary. Each shrinks exponentially at the same rate. The first maximum value of the transient current in any phase is greatest if it occurs at such a time that the transient components lie as nearly as possible in the projection axis for that phase at the moment that the transient begins. For, in that case, about one-half a cycle later the first component will have overtaken the second and the resulting projection on the axis of the phase will have its greatest value. During this time, however, each of the components will have shrunk to $e^{-\frac{k}{\sigma} \frac{\pi}{p}}$ of their initial values. The first

FIG. 18

maximum current rush may be to an approximate value of

$$\frac{2 I_n}{\sigma} e^{-\frac{k}{\sigma} \frac{\pi}{p}} \quad (38)$$

where I_n is the maximum value of the exciting current before the transient begins. This approximate solution checks with that given by Doherty and Williamson although the latter is in a slightly different form. The vector diagram is given in Fig. 18, which is drawn at the moment that the transient begins. The projection axes of one phase of the stator winding and of one phase of the rotor winding are shown. The former is fixed in position while the latter rotates at a speed

Fig. 23. The oppositely rotating components of the single-phase field are now shown at $\bar{\phi}_{2a}$ are $\bar{\phi}_{2b}$. At a time angle $\omega t + \delta$ later the vectors shown in Fig. 23 will have moved to the positions shown in Fig. 24. It is important to observe that the oppositely rotating components of the single-phase field are exactly the same in Fig. 21 and in Fig. 24. That is, as far as the reaction produced in the single-phase winding is concerned, there is no difference between positively and negatively rotating fields provided they are always conjugate with respect to the axis of the single-phase winding. In the case of polyphase windings we have seen that positively and negatively rotating magnetic fields produce quite different effects.

A magnetic field that rotates *positively* with respect to a polyphase winding excites the latter so that it in turn produces another field which rotates *positively* and which lags behind the first by an angle determined by the relative generalized angular velocity of the rotating field and the polyphase winding, and the resistance and synchronous self inductance of the latter. The reaction of the polyphase winding is

FIG. 24

often analyzed in the following manner: The alternating current that is generated in each phase of the polyphase winding produces two component fields that are rotating in opposite directions with respect to the winding. Those component fields due to the different phases which rotate opposite to the exciting field sum up to zero if the phase circuits are symmetrical. The other component fields that rotate in the same direction as the exciting field are in space phase with each other and their resultant is thus n times any one component; where n is the number of phases of the polyphase winding. That is, we may consider that the current in each phase of a polyphase winding consists of two equal components, hereafter designated by the subscripts a and b , each equal to *one-half* of the *maximum phase current*. These two component currents produce equal but oppositely rotating magnetic fields. If the winding were single-phase each of these magnetic fields would exist, but with a symmetrical polyphase winding only the fields exist which rotate in the same direction as does the exciting field. Those that rotate in the opposite direction neutralize one another, so that their resultant is zero.

Let M_1 be the e. m. f. generated in one phase of the polyphase winding by *one ampere* of *either* the a or b component of the single-phase current when varying at the rate of one ampere per second. Similarly let M_n be the e. m. f. generated in the single-phase winding by one ampere of the a component of the polyphase current, provided that is the one which produces a magnetic field, when varying at the rate of one ampere per second. Thus defined the n -phase mutual inductance is n times the single-phase mutual inductance. If the single-phase winding is supplied with an alternating current having an angular velocity of ω and the winding is rotated at this same velocity, ω , with respect to the polyphase winding, one of the oppositely rotating fields due to the single-phase current will be stationary with respect to the polyphase winding and thus will generate no e. m. f. in it. The other field will rotate at a relative angular velocity of 2ω and generate an e. m. f., E , in each phase of the polyphase winding. If the single-phase current is I , the single-phase mutual

inductance is $M_1 = \frac{E}{2\omega I/2}$. If the single- and

polyphase windings are fixed with respect to each other and one phase of the latter is directly opposite the former, the oppositely rotating fields produce equal e. m. fs. in time phase with each other in this phase of the polyphase winding. If E is still the e. m. f. generated in this phase of the polyphase winding the e. m. f. due to *one* of the component fields is $E/2$ and the single-phase mutual inductance is as before M_1

$$= \frac{E}{2\omega I/2}; \text{ where } I \text{ and } \omega \text{ are the current and its}$$

angular velocity in the single-phase winding. If the two windings are fixed with respect to each other and balanced currents of I amperes per phase are supplied to the polyphase winding the polyphase mutual inductance is the e. m. f. generated in the single-phase

winding divided by $\frac{\omega I}{2}$; where ω is the angular

velocity of the polyphase currents and I is the current per phase. Thus measured, the n -phase mutual inductance will be n times the single-phase inductance.

Let us assume that we have a three-phase winding fixed in position and a single-phase winding which is rotating in the positive direction at an angular velocity of p radians per second. If the single-phase winding carries a current having an angular velocity of ω radians per second there will be produced in the air-gap two rotating fields, one traveling in the positive direction at an angular velocity of $(\omega + p)$ and the other in the negative direction at a velocity of $(\omega - p)$ radians per second. If p is greater than ω both of these fields travel in the positive direction. The following relations can be worked out on the assumption that ω is either greater or less than p . In accordance with the established custom when analyzing polyphase induction

motors and generators, we will choose the first of these assumptions, *viz.*, that ω is greater than p .

The alternating current in the single-phase winding having an angular velocity, ω , produces two oppositely rotating fields each having this same angular velocity. The single-phase winding, having a positive angular velocity of p radians per second, gives to each of these fields an added angular velocity, so that one rotates positively with an angular velocity of $\omega + p$ and the other negatively with angular velocity of $\omega - p$ radians per second. Each of these fields produces by its action on the polyphase winding a rotating field which has the same angular velocity. This is illustrated in Fig. 25. In this figure A_1 represents the fixed axis of one phase of the polyphase winding, and A_2 represents the axis of the single-phase winding; the latter having a positive angular velocity of p radians per second. The oppositely rotating fields due to the single-phase current, which has a complex angular velocity of $-\alpha + j\omega$ radians per second, are represented by the vec-

FIG. 25

tors $\bar{\phi}_{2a}$ and $\bar{\phi}_{2b}$. The former has an angular velocity of $-\alpha + j(\omega + p)$ and the latter a velocity of $-\alpha - j(\omega - p)$ radians per second. Since these component fields are proportional to the current in the single-phase winding, this current can be divided into similar components as indicated in the figure, $\bar{I}_{2a}$ and $\bar{I}_{2b}$. Observe that each of these component currents is one-half of the maximum value of the single-phase current, and that at any moment the actual current in the single-phase winding is their vector sum. The first of these rotating fields, $\bar{\phi}_{2a}$, produces a current in the short-circuited polyphase winding $\bar{I}_{1a}$ where

$$\begin{aligned} \bar{I}_{1a} &= \frac{-\bar{I}_{2a} M_1 (m + j p)}{r_1 + (m + j p) L_1} \\ &= \frac{-\bar{I}_{2a} M_1 (m + j p)}{Z_{1(m+jp)}} \end{aligned} \quad (39)$$

M_1 is the single-phase mutual inductance, $m = -\alpha + j\omega$ is the generalized angular velocity of the single-phase current, r_1 and L_1 are respectively the

resistance and synchronous self inductance of the polyphase winding. The other rotating field $\bar{\phi}_{2b}$ produces a current in the short-circuited polyphase winding, $\bar{I}_{1b}$, which has a *negative* angular velocity of $\omega - p$ radians per second. In this case the current is:

$$\bar{I}_{1b} = \frac{-\bar{I}_{2b} M_1 [-\alpha - j(\omega - p)]}{r_1 + [-\alpha - j(\omega - p)] L_1} \quad (40)$$

Each of these polyphase currents produces two oppositely rotating component currents in the single-phase winding. The sum of the components which rotate in the same direction must of course be equal to the initial components rotating in the corresponding direction that were assumed to exist, *viz.*, $\bar{I}_{2a}$ and $\bar{I}_{2b}$. By the principle already established the rotating field due to $\bar{I}_{1b}$, produces the same effect in the single-phase winding as would a current of the same magnitude which rotates positively and is always conjugate to $\bar{I}_{1b}$ with respect to the axis of the single-phase winding. It is readily seen that this conjugate current, $\bar{I}_{1bc}$, is

$$\begin{aligned} \bar{I}_{1bc} &= \frac{-\bar{I}_{2a} M_1 [-\alpha + j(\omega - p)]}{r_1 + [-\alpha + j(\omega - p)] L_1} \\ &= \frac{-\bar{I}_{2a} M_1 (m - j p)}{Z_{1(m-jp)}} \end{aligned} \quad (41)$$

The stator current $\bar{I}_{1a}$ and the conjugate current $\bar{I}_{1bc}$, which replaces $\bar{I}_{1b}$, both rotate positively and their resultant effect on the single-phase winding is thus the same as the effect of their vector sum. The positively rotating component of the single-phase current is thus given by:

$$\begin{aligned} 2\bar{I}_{2a} &= \frac{-(\bar{I}_{1a} + \bar{I}_{1bc}) 3 M_1 (-\alpha + j\omega)}{r_2 + (-\alpha + j\omega) L_2} \\ \bar{I}_{2a} &= \frac{-(\bar{I}_{1a} + \bar{I}_{1bc}) 3/2 M_1 m}{Z_{2m}} \end{aligned} \quad (42)$$

These characteristic equations may be written thus:

$$\bar{I}_{1a} Z_{1(m+jp)} + \bar{I}_{2a} M_1 (m + j p) = 0 \quad (43)$$

$$\bar{I}_{1bc} Z_{1(m-jp)} + \bar{I}_{2a} M_1 (m - j p) = 0 \quad (44)$$

$$\bar{I}_{2a} Z_{2(m)} + (\bar{I}_{1a} + \bar{I}_{1bc}) \frac{3 M_1}{2} m = 0 \quad (45)$$

In these equations it is assumed that any impedance outside the armature and field circuits is negligible, otherwise the zeros at the right of the equality signs would be replaced by the proper *fall in terminal pressure*.

If $\bar{I}_{1a}$ and $\bar{I}_{1bc}$ as determined by the first two equations are substituted in the third equation, the latter becomes, on dividing by $\bar{I}_{2a}$:

$$\begin{aligned} Z_{2(m)} - 3/2 M_1 m \left(\frac{M_1 (m + j p)}{Z_{1(m+jp)}} \right. \\ \left. + \frac{M_1 (m - j p)}{Z_{1(m-jp)}} \right) = 0 \end{aligned} \quad (46)$$

If the values of the impedances are substituted, this reduces to the following cubic in m :

$$m^3 + \frac{(k_1(1 + \sigma) + k_2)m^2}{\sigma} + \frac{(k_1^2 + 2k_1k_2 + \sigma p^2)m}{\sigma} + \frac{(k_1^2 + p^2)k_2}{\sigma} = 0 \quad (47)$$

where $k_1 = r_1/L_1$, $k_2 = r_2/L_2$ and $\sigma = 1 - \frac{3M_1^2}{2L_1L_2}$

r_1 and r_2 are the resistances of one phase of the polyphase winding and of the single-phase winding; L_1 and L_2 are the synchronous self-inductance of the polyphase winding, and the self inductance of the single-phase winding. At least one root of a cubic equation must be real and since the coefficients are all positive this root must be negative. This indicates that one of the components of the single-phase current is a diminishing direct current. The other roots of the cubic equation are conjugate imaginaries. This indicates two alternating currents, having positive and negative angular velocities but the same rate of diminution. In the polyphase winding, however, the three components of the current will all have different angular velocities. The first component of the single-phase current will produce a current having an angular velocity of p radians per second and the same rate of diminution that it itself has. The second component of the single-phase current, having a positive angular velocity will produce a current which has an angular velocity of approximately $2p$ radians per second. The third component of the single-phase current having a negative angular velocity, produces a current in the polyphase winding of very small angular velocity. The sum of the angular velocities of these two latter components of the polyphase current is exactly $2p$, and each diminishes at the same rate as does the alternating current in the single-phase winding.

A literal cubic equation is practically impossible to solve but if numerical values are given to k_1 , k_2 and σ , the real root can be found to any degree of approximation by Horner's method. The equation may then be reduced to a quadratic, the roots of which can be readily found. Approximate values of the roots may be found as follows: The largest term in any of the coefficients is p^2 . With a 60-cycle machine this would be 142,122. The ratios of resistance to self-inductance k_1 and k_2 , are of the order ten, while σ is of the order one-tenth. For these values of k_1 , k_2 and σ the real root of the characteristic equation is approximately

$$m = -k_2/\sigma \quad (48)$$

The degree of approximation of course depends upon the values of the constants. If $k_1 = k_2 = 1.0$, $\sigma = 0.1$ and $p = 377$;

$$m = -10.06$$

whereas the approximate value would be

$$m = 10.0$$

In this case the error is about one-half of one per cent; which is better than the analysis warrants.

Since the sum of the roots must be the coefficient of m^2 in the characteristic equation with its sign changed and since the remaining roots are conjugate imaginaries of the form $-\alpha_2 \pm j\omega$ we have

$$-k_2/\sigma - 2\alpha_2 = -\frac{k_1(1 + \sigma) + k_2}{\sigma} \quad (49)$$

That is:

$$\alpha_2 = -\frac{k_1(1 + \sigma)}{2\sigma} \quad (50)$$

Furthermore since the product of the roots is equal to the last term in the characteristic equation we have:

$$\alpha_1(\alpha_2^2 + \omega^2) = (k_1^2 + p^2)k_2/\sigma$$

From this, the approximate value of ω is seen to be

$$\begin{aligned} \omega &= \sqrt{p^2 - (\alpha_2^2 - k_1^2)} \\ &= p - \frac{\alpha_2^2 - k_1^2}{2p} \quad \text{approximately} \end{aligned} \quad (51)$$

For the assumed values of k_1 , k_2 , σ and p the calculated values of α_2 are ω are:

$$\alpha_2 = 5.497$$

and

$$\omega = 376.73$$

For the same values of the constants the approximate values of α_2 and ω are:

$$\alpha_2 = \frac{1 \times 1.12}{2 \times 0.1} = 5.50$$

$$\begin{aligned} \omega &= 377 - \frac{5.5^2 - 1}{2 \times 377} \\ &= 376.96 \end{aligned}$$

It is readily appreciated that for such values of the constants as were chosen the roots are approximately

$$m' = -k_2/\sigma \quad (52)$$

$$m'' = -\frac{k_1(1 + \sigma)}{2\sigma} \pm j p \quad (53)$$

It may be desirable, however, to extend the analysis so that it will apply to the case in which it is necessary to consider the constants of circuits outside of the machine itself. In that event the approximate values of the roots may not be sufficiently accurate. Again if the constants are considerably larger, as for example:

Let $k_1 = 15$, $k_2 = 20$, $\sigma = 0.15$ and $p = 377$ the actual values of m are:

$$m' = -143.2 + j 0$$

$$m'' = -52.57 \pm j 360.3$$

The approximate values of m are:

$$m' = -133.3$$

$$m'' = -57.5 \pm j 373$$

In this case the error in the approximate calculation is quite considerable.

The general principle that determines the magnitude of the various component currents is that the resulting distribution of magnetic field in all parts of the machine

The direct-current component of the single-phase current has an initial value of $I_{2a}' + I_{2b}'$ which is $I_{20} \frac{(1 - \sigma)}{\sigma}$. The alternating component of the single-phase current is equal and opposite to this initially, but one-half cycle later the vectors representing all of the component currents are in phase. During this time, however, the direct and alternating components have shrunk different amounts. The first maximum value of the single-phase current will be, approximately:

$$I_{20} \frac{(1 - \sigma)}{\sigma} \left\{ e^{-\frac{k_2}{\sigma} \frac{\pi}{p}} + e^{-\frac{k_1(1 + \sigma)}{2\sigma} \frac{\pi}{p}} \right\} \quad (68)$$

For $k_1 = k_2 = 1$, $\sigma = 0.1$, this is $17 I_{20}$.

The component of the polyphase current which has an angular velocity of p radians per second is $\bar{I}_{1a}' + \bar{I}_{1b}'$ which initially equals $\frac{1 - \sigma}{\sigma} I_{1s}$. The com-

ponent which has an angular velocity of approximately

$2p$ is $\bar{I}_{1a}''$ which initially equals $-\frac{1 - \sigma}{2\sigma} I_{1s}$. The

component which has a very small angular velocity is

$\bar{I}_{1b}''$ which initially equals $-\frac{1 + \sigma}{2\sigma} I_{1s}$. The first

of these components shrinks at a rate of k_2/σ while each of the others shrinks at a rate of $\frac{k_1(1 + \sigma)}{2\sigma}$. No-

tice that initially the first component is opposite in phase to each of the others. Thus one-half cycle after the transient begins, the three components will be in phase. If the transient begins at such a time that the steady short-circuit current in one phase would naturally be passing through its maximum value, this phase will carry the maximum possible transient current one-half cycle later. This maximum transient current is approximately:

$$I_{1s} \left[\frac{1 - \sigma}{\sigma} e^{-\frac{k_2}{\sigma} \frac{\pi}{p}} + \frac{1}{\sigma} e^{-k_1 \frac{(1 + \sigma)}{2\sigma} \frac{\pi}{p}} \right] \quad (69)$$

for $k_1 = k_2 = 1$, $\sigma = 0.1$ this is $18 I_{1s}$, *i. e.* eighteen times the maximum value of the steady short circuit current.

TWO SINGLE-PHASE WINDINGS HAVING A CONSTANT RELATIVE ANGULAR VELOCITY

A current of angular velocity ω in one single-phase winding produces in the other winding currents having angular velocities of $\omega + p$ and $\omega - p$; where p is the relative angular velocity of the two windings. Each of these currents reacts on the first winding and produces additional currents having angular velocities of

$\omega + 2p$ and $\omega - 2p$. These currents in turn produce others in the second winding having angular velocities of $\omega + 3p$ and $\omega - 3p$, and so on ad infinitum. It is then evident that the solution of this problem cannot be reached by the method here developed unless all but a few of the component currents are neglected. The solution will not be attempted at this time.

Carson⁵ has suggested a functional form of solution of this problem and Dreyfus⁶ also gives a solution based on certain assumptions.

In conclusion the writer hardly needs to say that it has been his sole purpose to show how certain low-frequency transient conditions in electric machinery may be analyzed by a vector method. Before accurate results can be obtained by this method considerable experimental work is probably necessary in order to determine the most satisfactory methods of measuring the required constants. An interesting development would be the solution of the transient conditions in certain unsymmetrical arrangements of polyphase machines similar to those so ably discussed by Mr. Fortescue.⁷

Transient conditions may be the result of a variety of causes, one of which is short circuit. The vector method, however, is equally applicable in any case in which the original premises are reasonably true. The actual working out of a numerical solution is rather complex and this has been purposely avoided in order that the general principles might not be obscured a mass of calculation. Furthermore, it seemed best at this time not to attempt to generalize the theory and present it in such form that it would apply to combinations of electric machines that might even be unsymmetrical.

Appendix

For those who are interested in comparing the vector method of solution with the differential equations which apply to these problems the following development is given.

Consider a symmetrically wound three-phase induction motor having Y-connected stator and rotor phases as shown diagrammatically in Fig. 26. The stator and rotor currents are represented by the letters x and y respectively and their assumed positive directions are indicated by the arrows. Fig. 27 shows a development of the air gap. The progression of the phases, 1, 2 and 3 is toward the right for both stator and rotor, and the latter moves at a constant angular velocity of p radians per second toward the right.

Let r_1 , r_2 , L_1' and L_2' represent the resistances and self-inductances of one phase of stator and rotor respectively.

Let M_{xy} represent the mutual inductance between any

two phases of the stator. Due to symmetry these three mutual inductances are equal.

Let M_v represent the mutual inductances between any two phases of the rotor. These mutual inductances are likewise equal.

Let $2/3 M$ represent the maximum value of the mutual inductance between one phase of the stator and one phase of the rotor. At a time when the angular

FIG. 26

displacement of these phases of stator and rotor is pt the momentary value of this mutual inductance is $2/3 M \cos pt$, if the space distribution of the air-gap flux density is sinusoidal. This assumption of a sinusoidal distribution of flux density is not much in error if the motor is well designed. It is also necessary to assume that r_1 , r_2 , L_1' , L_2' , M_x , M_v , and $2/3 M$ are constant. This is commonly done in engineering practise.

FIG. 27

With the stator phases short-circuited as indicated in Fig. 26 the following differential equations may be written,—considering first phases 1 and 2 and then phases 2 and 3.

$$\left\{ r_1 x_1 + L_1' \frac{dx_1}{dt} - M_x \frac{dx_2}{dt} - M_x \frac{dx_3}{dt} + \frac{d}{dt} \left[y_1 \frac{2}{3} M \cos pt + y_2 \frac{2}{3} M \cos (pt + 120^\circ) + y_3 \frac{2}{3} M \cos (pt + 240^\circ) \right] \right. \\ \left. - \left\{ r_1 x_2 + L_1' \frac{dx_2}{dt} - M_x \frac{dx_3}{dt} - M_x \frac{dx_1}{dt} + \frac{d}{dt} \left(y_2 \frac{2}{3} M \cos pt + y_3 \frac{2}{3} M \cos (pt + 120^\circ) + y_1 \frac{2}{3} M \cos (pt + 240^\circ) \right) \right\} \right\} = 0 \quad (1)$$

There is a negative sign before M_x for the reason that positive currents in phases 2 and 3, for example, produce a flux through phase 1 which is opposite in direction to the flux that phase 1 produces through itself.

The equation which applies to phases 2 and 3 is:

$$\left\{ r_1 x_2 + L_1' \frac{dx_2}{dt} - M_x \frac{dx_3}{dt} - M_x \frac{dx_1}{dt} + \frac{d}{dt} \left[y_2 \frac{2}{3} M \cos pt + y_3 \frac{2}{3} M \cos (pt + 120^\circ) \right. \right.$$

$$\left. + y_1 \frac{2}{3} M \cos (pt + 240^\circ) \right] \left. \right\} - \left\{ r_1 x_3 + L_1' \frac{dx_3}{dt} - M_x \frac{dx_1}{dt} - M_x \frac{dx_2}{dt} + \frac{d}{dt} \left[y_3 \frac{2}{3} M \cos pt + y_1 \frac{2}{3} M \cos (pt + 120^\circ) + y_2 \frac{2}{3} M \cos (pt + 240^\circ) \right] \right\} = 0 \quad (2)$$

Since the sums of the stator and rotor currents are each equal to zero, we may substitute:

$$x_3 = -x_1 - x_2 \quad \text{and} \quad y_3 = -y_1 - y_2$$

Also replace $L_1' + M_x$ by L_1 . Multiply the second equation by 2 and add it to the first; again, subtract the second equation from the first. The results of these operations are respectively:

$$r_1 x_1 + L_1 \frac{dx_1}{dt} + \frac{2}{\sqrt{3}} M \frac{d}{dt} [y_1 \cos (pt + 30^\circ) + y_2 \cos (pt + 90^\circ)] = 0 \quad (3)$$

$$r_1 x_2 + L_1 \frac{dx_2}{dt} + \frac{2}{\sqrt{3}} M \frac{d}{dt} [y_1 \cos (pt - 90^\circ) + y_2 \cos (pt - 30^\circ)] = 0 \quad (4)$$

By a similar procedure differential equations may be written for phases 1 and 2 of the rotor. These equations will be found to be similar to (3) and (4) except that the signs before the phase angles will be reversed. Thus we will find that:

$$r_2 y_1 + L_2 \frac{dy_1}{dt} + \frac{2}{\sqrt{3}} M \frac{d}{dt} [x_1 \cos (pt - 30^\circ) + x_2 \cos (pt - 90^\circ)] = 0 \quad (5)$$

$$r_2 y_2 + L_2 \frac{dy_2}{dt} + \frac{2}{\sqrt{3}} M \frac{d}{dt} [x_1 \cos (pt + 90^\circ) + x_2 \cos (pt + 30^\circ)] = 0 \quad (6)$$

The following treatment was suggested to the author by Dr. F. L. Hitchcock as being the simplest method of reducing these equations to one containing a single variable.

$$\text{Let} \quad r_1 x_1 + L_1 \frac{dx_1}{dt} = Z_1 x_1$$

(Z_1 is an impedance operator,

$$\text{Similarly} \quad r_1 x_2 + L_1 \frac{dx_2}{dt} = Z_1 x_2$$

$$\text{Also} \quad r_2 y_1 + L_2 \frac{dy_1}{dt} = Z_2 y_1$$

$$\text{And} \quad r_2 y_2 + L_2 \frac{dy_2}{dt} = Z_2 y_2$$

If D and D^{-1} represent the direct and inverse differential operators, we shall have on integrating equations (3) and (4):

$$D^{-1} Z_1 x_1 + 2/\sqrt{3} M [y_1 \cos (pt + 30^\circ) + y_2 \cos (pt + 90^\circ)] = 0 \quad (7)$$

$$D^{-1} Z_1 x_2 + 2/\sqrt{3} M [y_1 \cos (pt - 90^\circ) + y_2 \cos (pt - 30^\circ)] = 0 \quad (8)$$

Solve these two equations for y_1 and y_2 .

per cent speed change per second, and the total speed change in $1/120$ second is $1/120 \times 100$ per cent = 0.833 per cent. This calculation assumes constant normal torque. Actually, the maximum value of the short-circuit torque is, say, six times normal. Assuming sine wave of torque the average value is $2/\pi \times 6 = 3.82$ times normal torque. Due to this increased torque the total speed change in $1/120$ second is 3.82×0.833 per cent = 3.18 per cent. Thus in $1/120$ second the rotor speed would have decreased 100 per cent to 96.82 per cent. The average speed during this interval would be 98.41 per cent, and in order to move the rotor one-half pole pitch at this reduced speed it would require $1/120 \times 100/98.41 = 0.00847$ second instead of $1/120$ or 0.00833 second. Thus a difference of only 0.00014 second. Obviously, the difference in magnitude of the peaks, due to the transient, in this small interval of time is not appreciable.

J. O'R. Coleman: A method of attack so useful and widespread in its application as that presented by Professor Lyon in his paper on "Transient Conditions in Electrical Machinery" is of vital interest from both a theoretical and practical viewpoint. Whenever a new method is introduced, doubt arises in the minds of many as to its application to practical cases. A limited amount of experimental work has been done along these lines, and has so far produced very favorable results.

These tests were performed on a General Electric 75-h. p., 900-rev. per min., 220-volt (full-load 180 amperes, no-load 60 amperes) three-phase induction motor operated as a generator.

FIG. 2—DIAGRAM OF CONNECTIONS FOR SHORT-CIRCUIT TEST ON AN INDUCTION GENERATOR

This machine was driven by a shunt motor of like size. The excitation for the induction generator was supplied by a 30-kw. synchronous generator. Although the circuit breakers would not remove this machine until late in the transient, the impedance of the path through the oscillograph shunts and the induction generator was so large compared with that of the short-circuiting switch that the disturbance of the synchronous exciter would not alter appreciably the record of the oscillograph. The diagrammatic arrangement of the units is shown in Fig. 2.

The vector diagram for a sudden short circuit occurring at no-load is shown in Fig. 3. The vectors I_{1B} , I_{1C} and I_{1A} represent the current in the three phases just before the short circuit occurs. The short begins at the moment just before the current in phase B reaches its positive maximum. At this moment I_{1B} , for example, breaks up into two components $I_{1B'}$ and $I_{1B''}$, whose vector sum is equal to the initial vector. After short circuit the terminus of the vector $I_{1B'}$ travels along the logarithmic spiral shown at a velocity of 360 circular radians per second and is damped at the rate of 96 hyperbolic radians per second. The terminus of the vector $I_{1B''}$ travels in a like manner along a logarithmic spiral as shown at a velocity of 17 circular radians per second and is damped at the rate of 60 hyperbolic radians per second. The value of the transient current at any instant is the projection of the vector sum of the two vectors on the time axis. The first maximum occurs about 0.008 of a second after the short circuit. The positions of the vectors at

this instant and the projection of their vector sum is shown in the diagram. The figure at the right of the diagram shows the resultant current obtained in this manner plotted in rectangular coordinates.

An oscillogram of the transient current during short circuit taken when operating at no load is shown in Fig. 4. It will be

noticed that the short circuit occurred in phases A and B nearly 0.001 of a second before that in phase C. Due to a very decided change in the slope of the transient curves of phases A and B when short circuit occurred on phase C, the latter point was taken as the point of short circuit in the calculations.

Fig. 5 shows a reproduction of the actual oscillogram compared

that for the required 350 volts, the gap length should be such as to give the minimum breakdown voltage for air at atmospheric pressure, or approximately 0.0003 in. in length. This seems at first sight to be impractical. It has, however, been found that use may be made of the well known fact that when conductors are separated by insulating spacers, breakdown tends to take place over the edge of the spacer at voltages lower than would be required for the gap. Trials have demonstrated that when the electrodes are separated by mica spacers of the thickness to give correct gap lengths, 3 to 5 mils, from the standpoint of voltage across the discharge, the breakdown voltage remains at the minimum value of 350.

Thus, a structure composed of a column of flat electrodes separated by mica spacers approximately 5 mils in thickness will operate as a valve, the critical voltage being equal to approximately 350 per gap, and the characteristic for voltages above this value being dependent on the resistance of the electrodes between plane surfaces. The discharge current capacity may be controlled by proper selection of disk area and thickness to give the characteristics required for any particular service. The voltage at which the discharge

FIG. 1—BREAKDOWN VOLTAGE OF SMALL GAPS IN AIR

starts is 350 per gap within close limits and the speed of operation has been found to be very high.

In the work of development of lightning arresters made on this principle, there were three major problems; namely, (1) experimental work consisting of the determination of characteristic relations and of the development of a suitable material for the electrodes, (2) design, consisting of the determination of the proper proportions to give the necessary performance characteristics and of the development of structures, (3) testing which consists of the determination of durability and performance characteristics by comparison in the laboratory with established forms of lightning arresters and by observation under actual service conditions.

In the *fundamental experimental work*, the initial attack was research with small glow discharges to determine breakdown voltage, the relation between voltage and current density, the distribution of voltage across minute gaps, the variation of voltage distribution with current density and various similar points.

From the data secured in these studies, it is desired to select a set of conditions which will give equal values for the breakdown voltage and for the voltage across the discharge while current is flowing and under which conditions the voltage across the discharge will be

approximately constant over a considerable range of current density.

For gaps up to 5 mils in length, the discharge consists almost entirely of the cathode dark space and cathode glow, both of which are practically constant in voltage over a large range of current density. When larger separations are used, a portion of the positive column is included, introducing a variation of voltage with current change. From this standpoint, the limit of gap length is about 0.005 in. which gives a voltage across the discharge which remains practically constant at 350 volts over any anticipated range of conditions.

Two means are available to secure the desired breakdown volts. If plane electrodes of ordinary manufacture are placed in contact, there will be actual contact at several points and over the rest of the surface there will be separations up to say 2 or 3 mils. For low voltages, the current will be that due to conductivity at the contacts. At voltages above 350 per gap however, the gaps break down at the points where the separation is correct for the minimum breakdown voltage and the discharge is then distributed over the face of the electrode by reason of the resistivity. The alternative and preferred means depends on the fact referred to above that, when conductors are separated by an insulating spacer, breakdown tends to take place over the edge of the spacer at voltages lower than required for the gap.

Trials demonstrated that when the electrodes are separated by mica spacers of the thickness required to give correct separation from the standpoint of voltage across the discharge (that is 0.003 in. to 0.005 in.) the breakdown voltage remains at the minimum value of 350.

The unit construction therefore becomes thin flat plates of resistance material separated by gaps of not more than 0.005 in. by mica spacers. For convenience in manufacture, the disks are made circular in form and the spacers in the shape of circular washers.

With these points fixed, *development work* was begun using disks of resistance material with various resistivities to determine the limit of resistivity required and to verify the findings of the research work by performance with structures of the size required for lightning arresters.

A considerable problem was encountered in the development of a material for the disks which would have the right characteristics and be feasible in manufacture. Ultimately however, a composition material was devised which is sufficiently durable, being mechanically more or less similar to porcelain, and which is electrically right, having a conductivity controlled by the methods of manufacture. With this material it has been found possible to manufacture disks of the desired resistivity and which, in sizes required for the structures, are remarkably true in dimensions. The nature of the material is such as to establish confidence in the permanence of characteristics.

It must be kept in mind, in considering the curves and data of Fig. 2 and 3, and Table 1 that they are based on assumptions in factors which are of vital importance, namely, in the values of surge voltage impressed on the lines. Assumptions are also made in the values of surge impedance, but in this case the values given are known to be fairly representative. The other values given and calculated are, with a fair degree of accuracy, correct. Thus, while the intention is not to state that the maximum voltage which may be applied to insulation, protected by an electrolytic arrester on a 22 kv. line, for example is 83-kv., it is a fact that under the assumed conditions the voltage will be as shown for the various arresters. It will be noted from these data that although the values of resistance of the autovalve arrester are well below that of the electrolytic arrester, the permitted surge voltage is only slightly lower than for the electrolytic. This is due to the fact that there is a factor of safety of 25 per cent between the peak value of line voltage and the critical voltage with the

FIG. 4—7500-VOLT DISTRIBUTION TYPE AUTOVALVE ARRESTER

autovalve arrester while no such factor of safety exists with the electrolytic since the critical voltage is determined by the line voltage.

In addition to the factors which control performance required and performance delivered it is necessary in selecting or in designing lightning arresters to take account of economic factors. An arrester which gives perfect protection but which costs more to install and maintain than it is worth in saving in service and apparatus is not justified.

From this standpoint and since it is possible to make quite appreciable reductions in manufacturing cost by a reduction in disk area, it has been found desirable to develop a line of low-voltage arresters of reduced capacity for the protection of very small installations. In this line of arresters, a disk area of 15 sq. cm. is used giving the characteristics shown in curve Fig. 3 for the distribution type autovalve arrester.

In the average installation made with this size of arrester, the reduction in the "discharge current capacity" is off-set to some extent by the fact that

transformers are installed on the same system fairly close together and the energy of any particular disturbance is taken care of by several arresters in parallel.

Figs. 4 to 6 show the forms in which arresters involving the autovalve principle have been made. Fig. 4 shows the distribution type, primarily intended for protection of distribution transformers, and therefore made for cross arm mounting, in unit form, entirely self contained in a porcelain case and with leads for

FIG. 5—STATION TYPE AUTOVALVE LIGHTNING ARRESTER UNIT

connection to the line and ground wire. The station or large capacity arresters are built up of units such as are shown in Fig. 5. The assembly of these units into structures is shown in Fig. 6.

A change which has been made from the previous standard practise is in the use of three complete columns for a three-phase structure instead of the former standard, four phase legs in the "multiplex" connection. An interconnection between phase stacks is provided at the phase voltage point in each stack. This connec-

FIG. 6—PHASE ELEMENT OF 37-KV. STATION TYPE AUTOVALVE LIGHTNING ARRESTER

Rain sheds for gap and top units are removed to show structure.

tion is based on the thought that the requirements from the standpoint of discharge current capacity are fixed by the most severe conditions, which are those imposed by disturbance of external or atmospheric origin. Such disturbances are imposed on the three lines alike and in flowing to ground through the arrester when the multiplex connection is used, the charges from the individual lines flow first through the corresponding

phase legs and then together through the ground leg. The result is that the impedance of the path to ground from any wire is equivalent to four times the impedance of a single-phase leg. Since each phase leg is proportional to 58 per cent of line voltage, the total impedance is equivalent to that of a structure proportional to 2.32 times line voltage. With the connection used in the autovalve structures this impedance is reduced to that of an arrester for line voltage only. The performance is in this respect improved in the ratio of 2.32 to 1 while the material added is increased in the ratio of 3 to 2.32, in other words an addition of 29 per cent in the material used increases the performance by 132 per cent. In respect to the performance under the less severe conditions of surges of internal origin in which the voltage is applied between lines, this connection is the same as the former standard connection.

Tests for establishment of the various characteristics referred to and for proof of the performance and durability of the structures resulting have been made both in the laboratory and by observation of results in service.

For the early laboratory work, use was made of a testing equipment consisting of a condenser of 0.2 microfarads capacity, capable of being charged to a maximum voltage of approximately 130,000, together with the necessary charging apparatus and discharge circuit. For later tests it has been found desirable to extend the range of voltage over which performance of the structures could be determined in the laboratory and accordingly a duplicate testing equipment was provided and arranged for connection either in multiple or in series with the original equipment. The available maximum voltage is thus approximately 250,000 with a capacity of 0.1 microfarad with an alternative of 120,000 volts and 0.4 microfarad.

FIG. 7—CONNECTIONS FOR SURGE TESTS

Tests for durability consist in general of the connection to the arrester of a power voltage of the maximum value for which the arrester is intended and the simultaneous discharge through the arrester of a condenser such as to give the assumed maximum of double the peak value of line voltage across the arrester. Where it is possible, that is with the arresters for the lower voltages, or smaller capacities additional tests are made at surge conditions just under the flashover limit. It was intended to determine something in regard to the

arrester life by a count of the number of discharges of double line voltage peak value required to cause some sort of failure, but practically indefinite tests do not cause any observable change in the arrester either from the standpoint of performance or appearance. As the surge conditions are increased in intensity, failure occurs by flashover at a voltage of the order of 15 to 20 times the voltage for which the arrester is designed. When surges just below the value necessary to cause flashover are repeatedly applied until failure occurs, the type of

FIG. 8—TYPICAL VOLT-AMPERE CURVES FOR AUTOVALVE AND ELECTROLYTIC LIGHTNING ARRESTERS

- 1 = Distribution Autovalve
- 2 = Electrolytic
- 3 = Station Autovalve
- 4 = Critical Voltage Autovalve
- 5 = Critical Voltage Electrolytic

failure depends on the cycle of test. If the tests are close enough together to cause excessive heating, failures have been noted due to destruction of the valve characteristics and the consequent flow of power current. Parallel tests on commercial arresters of other types show the same general type of failure to occur under the same conditions, which are so much more severe than any we can expect, except in the case of a direct stroke that the test is interesting only as an establishment of limits. If the discharges are timed far enough apart to eliminate excessive heating, the life of the structure seems to be indefinite.

As would be expected, the only failures that have been observed in service to date have been due to flashover and the flashover point of the commercial design has been increased considerably from the early samples with which this trouble was noted in the field. The total failures of arresters installed in service to date are something under 1 per cent.

The testing method to determine performance characteristics is to discharge through the arrester condenser charges of various characteristics. The performance may be shown by means of volt-ampere curves determined by such tests in which the surge conditions are varied over a considerable range. The current through the arrester is measured by a spark gap measurement of voltage across a resistance of known and permanent value which is connected in series with the arrester. The voltage is determined by a direct spark gap measurement across the arrester.

The fact that consistent results of the type reported can be secured in this test demonstrates the remarkable

speed with which the autovalue arresters operate. The measurements of voltage across the arrester were made with a 125-millimeter sphere gap connected directly across the arrester. No resistance was used in series with the gap. In spite of the extreme speed of

such a gap, the discharge started in the arrester, and discharge currents of several thousand amperes flowed through the arrester before the sphere gap broke down. When this type of test is made with an arrester which has a high dielectric spark lag, as compared to that of the sphere gap used for measurement of voltage, the indicated voltages will be determined in general by the factors which control initial breakdown of the arrester rather than by the impedance drop in the arrester. This does not mean that in such a case the measurements are untrue, but merely that they give no dependable indication as to the discharge impedance of the arrester.

The circuit used in these tests is shown in Fig. 7 and typical volt-ampere curves for both the distribution and station type arresters are shown in Fig. 8. For comparison a volt-ampere curve of a standard electrolytic arrester is also shown in Fig. 8. The data of Table I and the curves based thereon shown in Figs. 8 and 3 are calculated from resistance values determined from the volt-ampere curves of voltage corresponding to the assumed maximum permissible surge voltage.

The tests under service conditions give in general less specific information than laboratory tests, but they are valuable from the fact that they act as a sort of a court of last appeal. A total of 527 units has been installed on lines ranging up to 25,000 volts, both in the factory and on lines of various operating companies for periods up to 17 months. There failures have been observed with low voltage distribution units installed at the beginning of last year and the conditions were such as to point almost conclusively to flashover as the cause of failure. Several other failures were noted among the earliest arresters installed and these failures are known to have been caused by errors in design which were discovered after the arresters were installed. The major portion of these service installations were

made with 2500-volt distribution arresters of an early design, very close to the present type but using a disk area of 8.5 sq. cm. These tests, while they do not furnish specific values for the characteristics such as are available from laboratory tests, give final proof of the fundamentals, and thus add sufficient support to the laboratory tests to assure the results shown in Figs. 2 and 3.

It is fitting that mention should be made that the work reported here has been contributed by a considerable group of people in various degrees, but each in important measure. These include Dr. Slepian, the originator of the device and Messrs. G. M. Little, I. R. Smith, L. R. Golladay, S. M. Pineles, and E. J. Haverstick as well as the writer.

Discussion

D. W. Roper: The designers of the arrester described in Mr. Atherton's paper, having the courage of their convictions that they had a real lightning arrester, were willing to submit

FIG. 1

it to the scrutiny of the "laboratory" that we have in Chicago, for comparing the performances of various types of arresters.

The results of this scrutiny were entirely favorable. I think it would be quite unsafe at this time to give the arrester our unqualified approval, but there can be no objection to a modest statement that the results so far have been favorable. In fact we are placing more arresters of this design on our lines this year.

The test of this arrester was unsatisfactory in one respect during the past year. From a scientific viewpoint, the results were disappointing because we had so little lightning, the amount being only about 30 or 40 per cent of the average for the past ten years. However, there were one or two storms that gave us some interesting data. In one of them two arresters were affected at the same time. Fig. 1 is a diagram of the installations:

The sketch shows a substation feed system, distribution circuits, four-wire, three-phase, with the grounded neutral. The two arresters, indicated by the X's, were on different circuits, so that there was no actual or line connection between the two except around through the station. In one severe

proof that there is a minimum breakdown voltage at atmospheric pressures, and by extrapolation from curves taken at lower pressures, there is very definite proof that the voltage rises above this minimum breakdown voltage when the gap length gets sufficiently short.

K. B. McEachron: The application of the flow discharge to lightning arrester service as demonstrated in Mr. Atherton's paper is very interesting. We have been in the habit of associating the glow discharge with currents of very small value and it is surprising, indeed, that an arrester built on this principle should be able to handle thousands of amperes even for a very short interval of time.

As a matter of fundamentals, I would like to ask the author what determines the change from the glow discharge to the arc discharge with a given area of electrode. If it is a question of current and time, which in this case means energy, what is the relation between these quantities which marks the borderline between the glow and the arc discharge?

I am also interested in knowing the method used by the author when he found as a result of test that a current of several thousand amperes passed through the arrester before the sphere gap connected in parallel with the arrester broke down. In other words, how was the speed of the arrester measured?

A. L. Atherton: There are one or two points brought out on which comments are desirable. First, I want to acknowledge the assistance that was rendered us in the development work by the cooperation of Mr. Roper in Chicago. We were very fortunate to be able to place the trial arresters of his system where he has collected data for comparison and where his ideas are so definitely crystallized. One point which he has brought out is of special interest. During the season three failures occurred among the trial arresters installed in Chicago. A close examination was made of the arresters and every indication was that those failures were by flashover outside of the column of disks between the casing and the column. On calculating back from the line characteristics and the arrester characteristics, it developed that the surge voltage to cause such a failure must have been extremely high, as stated by Mr. Roper. In fact, it probably was a service condition that would result in the failure of any type of distribution arrester now available. However, we have felt it advisable to make changes to raise the flashover point since a ready means was at hand. Moreover, an increase has been made in disk area since the trial arresters were built so that the protection afforded has been increased to about double or a little over, giving voltages at the arrester something under half those which were encountered in the trial installations in Chicago. These two changes increase the factor of safety against flashover many times.

Dr. Steinmetz, in speaking of the test, brought out a point of great interest and one on which a great deal of work has yet to

be done. The matter of proper timing of measuring gaps is hard to handle, and the results are rather obscure and hard to translate. Of course, in practically all of the tests that are made on lightning arresters in the laboratory, measurements are made with gaps of which the timing is under control.

The results reported in the paper were selected as rather startling because the gaps that were used in those tests were without any retarding means. They were as rapid as they could be under the test conditions. It is an interesting and valuable point that the results secured with such gaps checked reasonably with what would be expected from the characteristics of the material put into the arrester. That simply demonstrates that the arrester itself is a very high-speed device.

The general question, mentioned in one discussion, of the heat generated in the gaps and the effects to be anticipated from this heat is best evaluated by reference to the tests. Single-column distribution-type arresters have been subjected to repeated discharges of approximately 7000 amperes which is several times the maximum current anticipated in service, and with a duration of the order of that of the surges met in service. After many such surges, tests and visual examination showed the disks to be unchanged.

It is also interesting that this same sort of energy concentration is present in all high grade arresters, since the same energy has to be handled by all arresters with equal discharge resistance. In general, if we assume the manufacturer's descriptions to be correct, in the types of arresters in which puncture of solid material takes place in operation, the energy is concentrated more than it is in this arrester since the total current is stated to flow through a few small punctures. In the autovalue arrester the discharge is very definitely spread out over the area of the electrodes. This brings us to the first question raised by Mr. McEachron. The form of discharge between given electrodes is, as pointed out in the paper, determined by the electrode temperature. This naturally varies with power input and duration. In any given discharge the temperature gradually rises and, if the power and duration are sufficiently above service conditions, the electrode temperature will reach that required for an arc. At this time quantitative data as to limits are not fully available. It is established however that maximum anticipated service conditions, excepting direct strokes of lightning must be greatly exceeded before the glow discharges change to arcs.

As to the inference of speed of the arrester from the tests with parallel gap, it is a safe assumption that if the gap with no series resistance breaks down first the arrester will not break down, for the voltage across the gap is low after breakdown and the gap with leads is a small part of the total circuit. But the arrester did break down. Therefore its speed is of the order of that of the measuring gap.

Machine Switching Telephone System for Large Metropolitan Areas.

Review of the Subject—From the earliest forms of telephone switchboards to the modern types, the development of the switchboard has been marked by the increasing use of automatic methods to supplement the manual operation wherever this would result in better service to the public or more efficient operation.

In addition to all that has been done in developing and introducing automatic operations with manual switchboards, it has been found desirable and practicable to go further in the direction of introducing automatic operation in the telephone plant and a machine switching

system has been developed in which the bulk of the connections are established without the aid of an operator.

The complexity of a large metropolitan area and the exacting requirements which a machine switching system must meet are outlined briefly, and the system which has been developed to meet these requirements is described.

The application of the system to a typical large metropolitan area and the means provided for permitting its gradual introduction into the existing plant are discussed.

IT is the purpose of this paper to outline briefly certain important developments in connection with machine switching telephone systems and to discuss the application of the results of these developments to the problem of providing telephone service in large metropolitan areas.

The telephone was invented in 1876. Almost immediately thereafter it was recognized that, for it to attain its greatest field of usefulness, switchboards and switching centers would have to be established for effecting interconnection between subscriber's lines.

Professor Bell's vision of the future was given in a statement to prospective investors. He said:

"It is conceivable that cables of telephone wires could be laid underground, or suspended overhead, communicating by branch wires with private dwellings, country houses, shops, manufacturing, etc., etc.—uniting them through the main cable with a central office where the wires could be connected as desired, establishing direct communication between any two places in the city. Such a plan as this, though impracticable at the present moment, will, I firmly believe, be the outcome of the introduction of the telephone to the public. Not only so, but I believe in the future wires will unite the head offices in different cities, and a man in one part of the country may communicate by word of mouth with another in a distant part.

"Believing, as I do, that such a scheme will be the ultimate result of the telephone to the public, I will impress upon you all the advisability of keeping this end in view, that all present arrangements of the telephone may be eventually realized in this grand system."

EARLY DEVELOPMENTS

The only apparatus available at that time for this purpose was that employed in telegraph, messenger, fire and burglar alarm services. Some of this apparatus, such as wire, insulators, batteries, annunciators, etc., was found to be useful in the new art; other apparatus had to be developed. The switchboards of that day

employed this apparatus. They were small in size, and could accommodate only a limited number of lines.

It soon became evident that the requirements of the telephone exchange service demanded signaling and switching equipment different from that employed in any of the other branches of the electrical industry, and it became necessary to create an entirely new art, involving many branches of science, before commercial telephone service could be given on an adequate scale.

FIG. 1—EARLY TYPE SWITCHBOARD

The switchboards grew from small boards, capable of handling a few lines, as shown in Fig. 1, to the very complex arrangements providing signaling, switching, and transmission facilities for as many as ten thousand lines in a single board, of the type shown in Fig. 2.

As the subscribers increased in number it was found that beyond a certain point it was no longer practicable or economical to have all of the subscribers' lines brought to one center. It was therefore necessary to have several centers, the number depending upon many

*Presented at the Midwinter Convention of the A. I. E. E.
New York, N. Y., February 14-17, 1923.*

factors, the most important of which are the size and telephone needs of the community.

The consequence of all this is that in large metropolitan areas the number of centers is large, and the trunking system complex, as each center must be provided either directly or indirectly with trunks to every other center.

As an illustration, take the New York Metropolitan area, shown in Fig. 3, where the telephone plant is of

FIG. 2—MODERN TYPE COMMON BATTERY SWITCHBOARD

the greatest intricacy because of the very large number of subscribers served. There are at the present time 158 central office switchboards, many of them having equipment for 10,000 lines. These offices and the associated plant provide for intercommunication between 1,400,000 telephones, and approximately two

FIG. 3—MAP SHOWING LOCATION OF CENTRAL OFFICES IN NEW YORK METROPOLITAN AREA

trillion possible connections. It is estimated that by the year 1940 there will be 300 central office switchboards within the New York Metropolitan area, serving some 3,300,000 telephones—or nearly two and a half times the present number.

MANUAL SWITCHBOARDS

The system most commonly employed today for connecting subscribers' lines together is the so-called "manual" system; that is, a system in which operators are employed to make the actual connections between subscribers' lines, although so many of the functions are performed automatically that, except in name, it is to a large degree automatic.

It is a long step from the early switchboards to the modern common battery multiple manual switchboards. The history of the development of switchboard equipment and apparatus shows that enormous progress has been made in this art in a comparatively few years. As the telephone subscribers have grown in number and as the amount and complexity of the traffic have increased, it has been only by the most intensive development that it has been possible to keep ahead of the demand for telephone service, and that telephone engineers have been able to get the speed, efficiency and accuracy that are obtained today in so-called manual operation. It is worthy of note in this connection that the attainment of these ends was made possible by the extensive introduction of automatic features.

A very brief description at this point of the type of manual switchboard more commonly employed will be helpful.

In this switchboard the subscriber's line terminates at the central office in so-called "jacks." Associated

FIG. 4—DIAGRAM SHOWING MANUAL INTEROFFICE CONNECTION

with each line is a lamp, individual to it, which automatically lights when the subscriber removes his receiver from the hook. This serves as a signal to the operator that a connection is desired.

The operator answers this call by inserting one end of a cord in the jack associated with the calling subscriber's line, operates a listening key which connects her telephone set to the subscriber's line, and asks for the number desired. When this is obtained the operator completes the connection by inserting the other end of the cord in the jack of the desired subscriber's line, and the subscriber's bell is rung. Suitable lamp signals are provided so that the operator may know when the called subscriber answers, when either subscriber desires further attention, or when either or both of them have finished talking and have hung up their receivers.

If the subscriber desired is connected to a distant office, the operator receiving the call would, instead of

plugging directly into the subscriber's line, directly connect the subscriber's line to a trunk terminating in the desired office, where the connection would be completed by a second operator, known as the "B" operator, as shown in Fig. 4. Such communication between the two operators as is necessary to establish this connection takes place over a special pair of wires known as a "call circuit."

The method, of which the above is a bare outline, is that used in completing ordinary connections. Different arrangements and different operating methods have to be provided for handling short haul toll calls, long distance calls, calls from coin boxes, and calls of many other kinds.

In the simplest types of manual systems, the subscriber, in order to signal the central office, turns a crank thus operating a magneto generator. This throws a drop in front of an operator at the central office. In the switchboards developed to meet the needs of the larger areas, electric lamps are substituted for the drop, and relays automatically controlled by the subscriber bring them into play at the proper time. Electric lamps which serve as visual signals to the operator to indicate the status of the connection are also associated with the cords that the operator uses for connecting subscribers together. The operation of these lamps is automatic and is under the control of the switchhook at the subscriber's station.

Many other arrangements of an automatic character have been developed and are used as occasion requires—not merely because they are automatic in character but only when it has been established that they make for better service to the public or for efficiency and economy of operation, or both. Among these may be mentioned automatic ringing, automatic listening, and many forms of automatic signaling. Many of these arrangements are highly ingenious and contribute greatly to the efficiency and economy of operation. Thus, the trend of switchboard development has been more and more in the direction of automatic operation and automatic methods.

In addition to all that has been done in developing and introducing automatic operation with so-called manual switchboards, it has been felt for a long time that in large and complex telephone areas, such for example as New York City, the time would ultimately come when it would be desirable to go further in the direction of introducing automatic operation in the telephone system. This whole matter has been the subject of much thought on the part of engineers of the Bell System and, as a result, there has been developed and recently put into operation a system in which the work of establishing most of the local connections is done entirely by machinery.

The introduction of this system will eventually make a considerable reduction in the telephone company's requirements for operators which are becoming more difficult to fulfill year by year. Operators will be re-

quired, however, to handle toll and many special classes of local calls and for this reason, together with the constant growth of the business and the considerable period of time that will be required to introduce the new system completely, we can expect little or no reduction in the present operating forces for some time to come, and no operator will find herself out of employment on account of the introduction of the machine switching system.

MACHINE SWITCHING

It is the purpose of this paper to describe this system sufficiently in detail to give a general picture of it, but because of the limitation as to space no attempt will be made to go into the intricacies of circuits and apparatus, which doubtless would be of interest only to the telephone engineering specialists.

Among other requirements, the following must receive special consideration in the design of a machine switching system.

The functions to be performed by the telephone subscriber in getting a connection must be simple and easily understood.

It must work efficiently and with accuracy and speed, and of course must be capable of handling the various types of calls that the subscriber wishes to make.

The system must not require modifications in the existing rate structure, otherwise than desirable. If the rate structure calls for message register operation, coin boxes, etc., means must be provided for automatically operating the register and collecting the coins on such calls, and for preventing a charge on calls not answered, calls for free lines, busy lines, etc.

The system should employ, as nearly as practicable, the conventional numbering scheme.

It should work with the existing telephone network, so that its introduction does not require wholesale number changes and extensive rearrangement or the abandonment of existing switchboards or other plant. Its introduction must, of necessity, be on a gradual basis.

It must be sufficiently flexible in design to care for growth and such changing traffic conditions as occur from time to time.

In large telephone areas, such as the New York Metropolitan area, there is a great variety of calls to be handled and many different classes of service furnished the public, such as message rate, flat rate, official, coin box, non-attended pay station, attended pay station, special services such as information, etc. Not only individual lines but party lines, and private branch exchanges must be cared for, and provision must be made for thousands of toll messages which must be recorded, supervised and timed.

A call originating in a machine switching office in New York City may have as its destination any one of a great number of points. It may be for another subscriber in the same office or for one in another nearby

machine switching or manual office; it may be for one of a large number of suburban toll points, or it may be to some point in a distant city.

The machine switching system, which is the subject of this paper, meets these requirements. After long-continued laboratory experiments, supplemented by field trials, power-driven apparatus of the panel type has been found to be the most suitable, and is now in successful operation in New York City and in other large cities in the country.

GENERAL PLAN OF OPERATION

At the expense of some repetition it seems desirable, in order to give as clear an understanding as possible

FIG. 5—DESK STAND EQUIPPED WITH DIAL

as to the operation of the system, to first give a brief outline of how the call is handled and a description of the more important elements of the equipment, before going into a detailed description of the operation of the system.

The subscriber's station is equipped with the usual form of telephone instrument and, in addition, with a

FIG. 6—SUBSCRIBER'S DIAL

calling device known as a "dial," mounted at the base of the desk stand, as shown in Fig. 5. This dial has ten finger holes bearing letters and figures, as shown in Fig. 6.

In making a call the subscriber will, of course, first refer to the telephone directory. He will find in the

directory a listing that is only slightly different from that to which he is accustomed. Typical samples of this new form of telephone listing for New York City are shown in Fig. 7. As will be noted, these conform to the present manual listings, except that the first three letters of the office name are set out prominently. This numbering system will be discussed later in this paper.

Having secured the desired telephone number from the directory, which we will assume is "ACAdemy 1234," the subscriber will first remove his receiver from the hook and will hear the so-called "dial tone," which indicates that the apparatus is ready to receive the call. He will then insert his finger in the hole over the letter A, rotate the dial until the finger comes in contact with the metal stop shown in the picture, then release the dial, which will automatically return to normal. He will repeat this operation for the letters C and A, and in turn for the four numerals, 1, 2, 3, 4.

This operation of dialing on the part of the subscriber is exactly the same, whether the telephone number he desires is in a manual or in a machine switching office.

FIG. 7—TYPICAL EXAMPLES OF NEW FORM OF LISTING TELEPHONE NUMBERS

Similarly, the method employed by a subscriber who is connected to a manual office in getting a subscriber connected to a machine switching office, is the same as though the desired subscriber were connected to another manual office.

The progress of a call originating in a machine switching office is briefly as follows:

As will be seen from Fig. 8, the line of the calling subscriber, whom we will assume to be a subscriber in the Academy office, appears in a so-called "line finder" frame. When the subscriber's receiver is removed from the switchhook preparatory to dialing, the line is selected by a "line finder" and connected to an idle "sender" by means of a "sender-selector."

Upon completion of these operations which take but a fraction of a second, the dial tone is sent out to the calling subscriber as previously mentioned. When the subscriber dials, electrical impulses on a decimal basis are transmitted to the sender which receives and registers them, translating them in turn to the proper

basis for the control of the selectors which are not operated on a decimal basis. The sender automatically causes the particular "district selector" which is permanently associated with the line finder originally used, to select a trunk to the office desired.

Assuming that the call is for a subscriber in the same office, Academy, the trunk chosen will terminate at an "incoming selector" frame and the sender above referred to will cause the call to be routed through the incoming selector to a final selector, and thence to the particular line desired. When the connection is thus completed, audible signals will be sent back to the calling subscriber to indicate that the station is being rung or that the line is busy.

If the call had been for a subscriber in another machine switching office, namely, Pennsylvania, the call would be routed from the district selector to the office desired, either directly or through an "office selector" in case the total number of trunks to all offices is too large to be placed on the district selector multiple.

FIG. 8—DIAGRAM SHOWING CONNECTIONS FROM MACHINE SWITCHING TO MACHINE SWITCHING, MACHINE SWITCHING TO MANUAL AND MANUAL TO MACHINE SWITCHING.

These trunks terminate on incoming selectors at the Pennsylvania office which select the subscriber's line through final selectors, as described above.

If the call is for a subscriber connected to, say, the Worth Office, which is a manual office, the call would be routed from a district selector directly or through an office selector to the "B" board in the Worth Office, where the number desired appears in front of the operator at a "call indicator position" in the form of visible numbers on the keyshelf. The operator is advised of the trunk to which the call is connected by suitable signals, and the call is completed by plugging this trunk into the desired subscriber's line.

Calls originating in a manual office and intended for a machine switching office reach the machine switching office over trunks from the "A" operators in the manual office. At the machine switching end these trunks terminate in incoming selectors, which have access to the final selectors on which the subscriber's lines are

located. The selectors are under the control of a special group of senders, and operators are provided with suitable keys for setting up in these senders the number of the desired subscriber. These operators at the machine switching office receive the information as to the desired number from "A" operators in the distant manual office, exactly as is done in the case of manual operation.

The introduction of machine switching equipment does not require radical changes in private branch exchanges. The private branch exchange is provided with dials, and calls to the central office are dialed by the private branch exchange attendant or by the extension user in the same way that the ordinary subscriber dials. No change in the private branch exchange is required for handling incoming calls. An idle trunk in the private branch exchange group is selected by the mechanism in the machine switching office, in much the same way as an individual subscriber's line is selected.

NUMBERING SYSTEM

One of the unique advantages of the plan developed for designating telephone numbers, to which reference has already been made, is that it does not necessitate the abandonment of the existing manual listings. It requires no change except that the first three letters of the office name are set out more prominently. Simple as this change in the form of listing appears, until it was developed by the Bell System no satisfactory method of designating telephone numbers for machine switching offices in large cities was known.

Many plans had been proposed, to all of which there were serious objections. Some of them required changing the whole system of manual designation, others the use of combinations difficult for the subscriber to use. In small cities a numbering plan employing only digits is sometimes practicable, but in such a large area as we are considering, such a plan would involve seven digits. The subscriber's number would take the form of say 786-3549. Such numbers would be difficult for operators to use and for the subscribers to carry in mind and would require that every subscriber's number in the entire area be changed before the first machine switching office could be cut into service. With the new system, the subscriber's number and office in general remains as before. It is necessary to change only a few conflicting office names in order to make them fit into the system.

DESCRIPTION OF THE EQUIPMENT

A detailed description of each unit employed in this system would be impracticable, in this connection, but a brief description of the more important ones will be of interest.

Sender. The use of the sender makes practicable the introduction of machine switching in large metropolitan areas where, of necessity, the service conditions are extremely complex. It is, in effect, the brains of the system, dealing with the subscriber and controlling the selection until the destination is reached, as an

operator deals with the subscriber and controls the selection in a manual system. The number dialed conveys the same information to the sender in a machine switching system as the number spoken by the subscriber does to an operator in a manual system.

The sender is an arrangement of relays, sequence switches, and selectors, so worked out as to perform the following more important functions:

1. It receives a succession of electrical impulses from the subscriber's dial which are on a decimal basis, stores them and translates them to a non-decimal basis, corresponding to the particular group of lines and trunks that is involved in the path of the call.

2. It controls selecting mechanisms which build up the connection to the called party in such a manner that each mechanism is given the exact time required to perform its functions without any waste of time, independently of the rate received from the dial.

3. It makes the central office designations entirely independent of the arrangement of the trunk groups on the selector frames. This is a very important matter, inasmuch as it allows the selectors to be used to full efficiency. It provides the desired flexibility for growth and permits any desirable rearrangement of the trunks on the selector frames that the telephone company may find desirable at any time.

4. The sender is capable of distinguishing the class of office at which the connection terminates. That is, if the call is to terminate at a mechanical office, the sender will arrange to govern the selection accordingly. If the call is to terminate at a manual office, the sender recognizes this and arranges to send out impulses to the call indicator equipment in the manual office.

5. For the completion of certain calls, traffic conditions require the introduction of tandem centers as discussed later. The sender recognizes calls to be routed via tandem centers and arranges to handle these correctly. The tandem center may be manual or it may be mechanical, and the control must be determined accordingly.

6. Certain senders are arranged to serve lines supplied with coin boxes. These senders are arranged to make a test to determine whether a coin has been deposited and do not allow the connection to be cut through so that conversation can take place until the coin is deposited. If the subscriber does not deposit the coin, after a reasonable time has elapsed the sender connects an operator to the subscriber, and this operator notifies the subscriber of his omission. After the coin has been deposited, the sender allows the called subscriber to be rung and permits the conversation. In case the called subscriber is busy or does not answer, or if the call is to a free line, the sender returns the coin to the calling party. If the called party answers, the sender causes the coin to be collected.

The sender makes a test of the calling line after the subscriber has completed dialing, to insure the deposit of the coin, and recognizes whether a coin has actually

been deposited or whether some abnormal condition exists, in which case the call will be routed to an operator who causes an investigation to be made.

7. In large areas, such as the New York Metropolitan area, there are distant points, connection to which requires toll charges. In such cases the subscriber is instructed to dial a special operator who will ascertain his wishes, complete the call, and make the proper charge. Should a subscriber attempt to dial outside of his own local service area, his call will automatically be routed to an operator.

Panel Type Selecting Mechanism. An important mechanism of a machine switching system is the selector and its associated multiple bank. It is a device by means of which trunks or lines are connected together

FIG. 9—VIEW OF THE SELECTOR

as required. It performs the same function as the switchboard cord and plug which in a manual exchange can be plugged by the operator into any one of a number of jacks which are the terminals of trunks or lines.

Fig. 9 shows the mechanical elements of the selectors. The movable member corresponds to the cord and plug of the manual system and the fixed terminals or multiple, to which the movable member can make connection, corresponds to the jacks of the manual system.

Fig. 10 shows the fixed terminals or multiple to which the selectors connect. This multiple consists of flat punchings about $3\frac{1}{2}$ feet long and 1 inch wide overall. Each of these strips has lugs on each side with which the selectors can make contact. In this particular panel, three hundred of these strips are piled one above the other, separated by insulation, and securely bolted together, forming a panel about 15 inches high.

the top of the frame, just above the fifth bank, are located commutators as shown in Fig. 11, one for each selector. The multiple wiring of the brushes on the selector leads to other brushes which move over strips on these commutators, and thereby completes the connection from the movable selector to the rest of the circuit, thus avoiding flexible wire connections with

FIG. 12—SEQUENCE SWITCH ASSEMBLY

their attendant troubles. This commutator, also, performs the more important service of controlling the travel of the selector. Brushes moving over conducting segments separated by insulation produce impulses

FIG. 13—SELECTOR FRAME COMPLETELY EQUIPPED

which, when sent back to the sender, indicate to it the exact position of the selecting mechanism.

Sequence Switch. Another device of great importance is the "sequence switch," shown in detail in Fig. 12. It is operated through an electromagnetic switch from the same motor that drives the selectors.

The sequence switch may be described as a circuit controller or device whose function is to establish in a definite sequence such circuit conditions as are required in the operation of the system. It is made up of circular disks called cams mounted rigidly on a shaft. The plates of the cams are cut so that brushes come in

FIG. 14—GROUP OF TYPICAL SELECTOR FRAMES

contact with the plates only when the circuit is to be closed. The sequence switch can be stopped at any one of eighteen different positions as required, by the simple opening of the electromagnetic clutch.

There are many of these sequence switches used in this system, and the arrangement of cutting the cams varies, depending upon the particular circuit combinations which it is desired to establish.

Selector Frames. Fig. 13 shows thirty selectors with all of the associated mechanism mounted upon one side of a frame ready for operation in an exchange. Both sides of the frame are alike. Five panels of 100 lines each are mounted in this frame, one above the other, giving a total capacity of 500 trunks or lines. Thirty selectors, each capable of making connection with any one of the 500 trunks or lines, are placed adjacent to each other on each side of these panels; the entire frame thereby having a capacity of sixty selectors, each of which has access to 500 trunks or lines.

Immediately to the right of the selectors are the sequence switches and, under protective covers, such relays as are used in connection with the selectors upon the frame shown.

Selecting apparatus of this general type, but differing in details of design, is used during the different stages of the call as line finders, district selectors, incoming selectors and final selectors, reference to which has been made before. Fig. 14 shows a section of a machine switching office with some of the typical frames.

The use of apparatus of the substantial construction just described is made possible only through the use of the sender which receives impulses from the subscriber at the rate they are dialed and receives impulses from the selecting mechanism at the rate it is traveling. This obviates the necessity for restrictions in the design of either the dialing circuit or the selecting circuit, such as would be necessary if they were tied together.

Power Supply Arrangements. Since most of the operations normally required in handling a call in a machine switching office are carried out mechanically, it is evident that a considerably larger amount of power is required than with the manual system. Selectors and sequence switches are propelled mechanically by rotating

FIG. 15—POWER MACHINE AND CONTROL EQUIPMENT FOR TWO 10,000-LINE UNITS

shafts driven continuously by small motors mounted on each frame.

The use of small motors on each frame gives a flexible and reliable source of power particularly since the motors now being used are of the special "duplex" type developed for the purpose. They consist of two motor elements in one frame, one element being normally driven from the commercial power service and the other being driven by the telephone reserve storage battery to which it is automatically connected by a relay inside the motor when the regular power fails. A power failure, therefore, causes no interruption to the drive. The selectors are arranged so that not more than half in any one group are driven by the same motor which insures continuous service in case of motor failure.

The main power requirement is for direct current at about 24 and 48 volts which is furnished from motor generator sets (Fig. 15) of special construction to reduce noise, converting the commercial alternating or direct power current into current which is regulated as to

voltage and is free from variations which would cause noise in the telephone circuits.

Storage batteries (Fig. 16) floating across the current supply bus-bars insure regulation. In addition to stabilizing the voltage and reducing noise interference from the machines and between telephone circuits, the

FIG. 16—BATTERY ROOM FOR TWO 10,000-LINE UNITS

batteries perform the important function of keeping the exchange in operation during interruptions to the commercial power service. Small motor generators furnish current for ringing subscribers' bells and drive commutators supplying various tones and signals. Batteries or machines supply current for operating coin boxes and

FIG. 17—165 H. P. GAS ENGINE GENERATING SET FOR EMERGENCY USE

pulse machines provide impulses for the operation of certain of the machine switching apparatus.

Whenever practicable, two or more commercial power services from independent generating stations are secured, either of which will keep the office supplied. Where independent generating systems are not available a reserve gas engine supply (Fig. 17) is installed to take the place of the incoming power service, such engine

also being equipped for emergency operation on gasoline.

All of the essential power machines and batteries are provided in duplicate and as indicated, are arranged to come into action automatically wherever this is necessary to insure continuity of service in the event of loss of power or trouble with any of the power equipment. Alarms are provided to detect variations in battery voltage, blowing of fuses, stopping of machines or any failure of service on all power busses which feed energy to the telephone or signaling circuits. The power plant is thus designed to give an uninterrupted energy supply at all times even when the usual sources of power may have been temporarily discontinued.

DETAILED PLAN OF OPERATION

The following will give in some detail the plan of operation for handling typical calls between various types of offices in a large metropolitan area such as New York City.

Calls Originating in Machine Switching Offices. Fig. 18 shows schematically the path of a call originating in a machine switching office. The pair of wires of a subscriber's line is attached to one of the sets of fixed terminals in a panel bank appearing before a group of selectors of the type which has been described. By putting fewer lines in these panels and increasing the number of selector brushes, we attain the speed neces-

FIG. 18—DIAGRAM OF LINE FINDER, DISTRICT AND OFFICE FRAMES

sary at this stage of the connection. These selectors are called "line finders," since their function is to find calling lines. The terminals correspond to the answering jacks and the selectors to the "A" operators' answering cords of the manual system.

When the subscriber removes his receiver, he closes the circuit of his line, causing a relay at the central office in series with his line, to operate. This relay causes an idle line finder, having access to his line, to trip the proper brush and then move upward to his line. At the same time a sender selector attached to that line finder is choosing, out of a common group,

an idle sender. The sender selector is a small selector of a type in which the brushes are driven by a magnet over contacts arranged as shown in Fig. 19.

The sender having been attached in this manner to the calling line, a low humming sound, known as the dial tone, is heard by the subscriber, advising him that the mechanism is ready for him to dial. The entire sequence of events just described takes place in a fraction of a second, so that ordinarily the subscriber finds the dial tone when the receiver reaches his ear.

FIG. 19—SENDER SELECTOR

The subscriber now dials the required letters of the office name, and the numerals of the called number.

The pulses from the dial come over the subscriber's line through the line finder and sender selector to the sender which records and translates them to control the setting up of the connection. As soon as the connection has been established, the sender is released and is ready to be used for a new call, being kept in use only a few seconds for each call.

The first step in completing the connection is to choose an idle trunk in the proper direction. To the nearby offices there are groups of direct trunks, whereas the more distant offices are reached through tandem centers described later.

The line finder leads to the movable element of a panel selector known as a "district selector." This district selector has capacity for 450 working outgoing trunks, the other 50 trunks being used for control purposes. In a small city 450 trunks would be sufficient to reach all points, but in the case of the New York offices 450 outgoing trunks are not sufficient. Accordingly, only a few of the trunk groups outgoing from these offices leave directly from the district selectors. To obtain access to the remaining trunks there are, on every district selector frame, groups of trunks leading to so-called "office selectors." These office selectors are of the panel type and each has a capacity for 450 outgoing trunks.

The path of a call through a district and office selector will now be traced. The district selector starts upward under the control of the sender. As the district selector moves upward, it produces pulses by means of the brushes which slide over the commutator at the top of the selector. These pulses are transmitted back to the sender, and are there counted. When the sender has counted the number of pulses which indicates

to it that the district selector has proceeded to the proper position, the sender opens the fundamental circuit to the selector and causes it to stop. This method of controlling the movement of the selector is termed the reverse control method.

The first selection made chooses the set of brushes to be tripped into engagement with the terminals. Assume, as shown in Fig. 18, the desired trunk appears on the second panel from the bottom. Therefore, the district selector is allowed to make two pulses and is then stopped by the sender. The brush-tripping device is thus set in position to trip the second brush, and the selector is started again by a signal from the sender, which operation completes the process of tripping the brush.

The selector now continues upward, making a pulse for every group of trunks which it passes over, until, having reached the desired group, as indicated by the number of pulses counted by the sender, it is again stopped by the sender at the beginning of this group. The selector is now started again, and this time under its own control, hunts for an idle trunk in the group. Busy trunks are grounded on the third or signaling terminals, whereas idle trunks are open. A testing relay, associated with the selector, keeps the selector moving upward until a trunk with an open third wire is found, whereupon the selector stops, makes connection with this trunk, and renders it busy to other selectors by grounding the signaling strip.

This trunk, as indicated in Fig. 18, leads to an office selector. The same process is repeated by the office selector, under control of the sender, to trip first the proper brush, then choose the proper group, and finally to choose an idle trunk in the group. The connection is now extended to an outgoing trunk. The sender still remains attached to the connection, since it must still control the further setting up of the connection.

The sizes of the working trunk groups on district and office selectors can vary from 5 to 90, depending upon the traffic to be handled.

Calls Between Machine Switching Offices. If the call is for a subscriber in a machine switching office it is completed as shown in Fig. 20. This figure shows a diagram of the apparatus used to connect an incoming full mechanical trunk to a subscriber's line, whether this line is in the originating machine switching office or in another which must be reached over interoffice trunks.

The incoming trunk to the machine switching office terminates on an "incoming selector," which is of the type already described. The machine switching office has a capacity for 10,000 numbers, but the incoming selector has capacity of only 500 trunks, so that the same arrangement is employed as on the district selectors; that is, the incoming selector chooses one of a number of other selectors, called "final selectors," which have access to the subscribers' lines. Since each group of final selectors has access to 500 subscribers,

20 groups of finals will be necessary to care for the full 10,000 numbers. On the incoming selector frames, therefore, appear 20 groups of trunks, each group leading to a different frame of final selectors.

The method of selection is the same as described for the district and office selectors; that is, first the incoming selector, under control of the sender in the originating office, trips the proper brush, chooses the proper group, and finally chooses an idle trunk leading to a final selector. The final selector then goes through the process of brush, group, and subscriber's terminal selection. The terminal selection is under the control of the sender which counts line by line in the group of ten, until the desired one is reached. If the called line is idle, it is rung, and the calling subscriber is advised of that fact by hearing the audible ringing signal. If the called line is busy it is not connected, but an intermittent buzz, recognized as the busy signal, is sent back to the calling subscriber. If the called number is that of a P. B. X. having several trunks, the final selector automatically hunts for an idle one. If the

FIG. 20. DIAGRAM OF INCOMING AND FINAL FRAMES

final selector, after testing all the P. B. X. trunks finds them all busy, it sends back the busy signal.

As soon as the called line is reached, the sender is dropped from the circuit to be available for another connection. It is not held during the period of ringing, during the time that the busy signal is being given, if the line is busy, or during any part of the period of conversation.

It will be noted that the method of selection is not on a decimal basis. The first selection is to choose one of five brushes on the incoming selector as already explained; that is, we choose that particular fifth of the terminals in which the called line happens to be, and since $1/5$ of 10,000 is 2000, we choose the 2000 group desired. The next selection is by groups of 500, which is again non-decimal. This "translation," as it is called, of the number from the decimal notation, as dialed by the subscriber, into the notation as needed by the selectors, is taken care of very simply in the senders.

Calls from Machine Switching to Manual Offices. Calls from machine switching to manual offices are handled at the manual office on call indicator "B" positions. Fig. 21 shows a diagram of the equipment used to connect such a call to a subscriber in the manual office.

The call progresses through the district and office selector in the same manner as described for the machine switching call, but the trunk which it takes up leads to

FIG. 21—DIAGRAM OF CONNECTION FROM MACHINE SWITCHING TO MANUAL

a call indicator "B" position in the manual office selected. The operator is notified that a call has reached her position by the lighting of a lamp associated with the cord and plug in which the incoming trunk terminates. Upon perceiving this signal, she presses a display key associated with that trunk, and thereupon

FIG. 22—INCOMING TRUNK POSITION IN A MANUAL OFFICE ARRANGED FOR CALL INDICATOR OPERATION

the called subscriber's number is displayed on a bank of numbered lamps located on this operator's keyboard. The operator picks up the plug, tests the called line and, if it is found idle, plugs in; or, if it is found busy, she plugs into a special jack which is arranged to send the

intermittent busy tone back to the calling subscriber.

The called subscriber's number is displayed in the following manner. Associated with the operator's position, and with her call indicator, is a group of relays. When the display key is depressed, this group of relays is attached to the trunk. The sender which has meanwhile been waiting on the connection, is thereby given a signal, and sends the number called by means of code pulses which are received by the group of relays. These relays, in turn, light the set of lamps on the call indicator corresponding to the digits of the called number, as shown in Figs. 22 and 23. The code

FIG. 23—CALL INDICATOR AT AN INCOMING TRUNK POSITION IN A MANUAL OFFICE

pulses employed for sending this called number are positive and negative, strong and weak, and are translated by the sender from the decimal dial pulses to this type of pulse to reduce the time required and to simplify the receiving apparatus.

Incoming Calls from Manual to Machine Switching Offices. Calls from manual offices are handled at the machine switching office on the cordless "B" positions.

FIG. 24—DIAGRAM OF A CONNECTION FROM A MANUAL TO A MACHINE SWITCHING OFFICE

Fig. 24 shows a diagram of the equipment used to connect a call originating in a manual office destined for a subscriber in a machine switching office. Such a call is answered by the "A" operator in the manual office in the usual manner. She takes up the call circuit by depressing her call circuit key to the machine switching office desired, passes the called subscriber's number, and receives a trunk assignment in exactly the same manner as if the call were going to another manual office. The

cordless "B" operator, upon assigning a trunk, presses the assignment key of that trunk, which temporarily attaches her keyboard to a sender and simultaneously to the incoming trunk which she has assigned. As shown in Fig. 24, the incoming trunk terminates on an incoming selector which has access to final selectors on which the called number appears, in the same manner as described before.

The operator now sets up on her numbered keys the number desired, and this information is transmitted immediately to the sender. These keys, which lock mechanically, are released after a fraction of a second

FIG. 25—CORDLESS "B" POSITIONS IN MACHINE SWITCHING OFFICE

by a magnet controlled by the sender and are ready for the next call. The "B" operator's sender now controls the incoming and final selectors in the same manner as the subscribers' senders, causing the incoming selector to choose an idle trunk to a final selector having access to the desired group of 500 numbers. The final selector reaches its destination in the manner previously described and, as soon as the line is found, the sender is released.

Fig. 25 shows a line of cordless positions. The section at the left is the cable turning section, having nothing to do with the operation of the board.

Manual Positions Required in Machine Switching Offices. While regular calls between two subscribers will be completed in this system without the aid of operators, certain classes of calls, such as toll calls to suburban points and calls for discontinued or changed numbers, etc., will require the assistance of an operator. Special manual positions are therefore provided in the machine switching office for this service. These positions also care for cases where the subscriber may need the assistance of an operator for other reasons than the above, and are in addition to the cordless "B" positions previously described.

The operators are called "Special Service Operators." The subscriber signals them by dialing "Zero," which on the dial is also marked with the word "Operator." The connection then progresses in the same general manner, through the district and office selectors, as for

any originating call. An idle trunk appearing on the office selector leading to an answering jack before the special service operator is chosen and the sender released. Should a subscriber in any local service area dial a subscriber in another area, the sender will automatically route the call to a special service operator.

The special service operator in large areas has before her a number of cord circuits having one end terminating in a cord and plug. She also has upon a keyboard a set of keys similar to those described for the cordless "B" position, except that there are additional strips of keys upon which she can write up an office code. The operator answers the subscriber by inserting one of the plugs in the answering jack and, having ascertained the desires of the subscriber, directs the connection to the proper destination by setting up on her keys the proper numerical code. Senders are furnished for these positions so that, as soon as the information from the keyboard has been registered on the sender, the keys are released and are ready for another call.

The other end of the special service operator's cord circuit terminates in a district selector which, either directly or through other selectors, has access not only to trunks which the subscriber himself might call, but also to trunks leading to more distant offices which he cannot dial directly because they are toll points.

Tandem Operation. There are about 158 central offices in the area shown on the map, Fig. 3. While it is an essential requirement that any subscriber connected to any of these offices be able to reach any subscriber connected to any other office, it is obvious that to furnish trunks from each office direct to every other office would require a great number of long trunks in small groups carrying a very light load most of the time.

FIG. 26—TYPICAL TANDEM TRUNKING PLAN

In order to eliminate the inefficiency that such an arrangement would entail, it has been the practise in manual operation to handle the traffic from one part of the area to another part of the area over main trunk routes. The collecting and distributing points on these trunk routes are known as "tandem centers," and the plan of operation is known as "tandem operation."

Fig. 26 shows an arrangement of offices in a typical tandem trunking plan. Offices marked M are local offices, either manual or machine switching. The office marked T is a tandem office. If a call is originated by a subscriber in office M-1 for a subscriber in offices

M-4, M-5, or M-6, to which no direct trunks are provided, the call is routed at office M-1 to trunks terminating at tandem office T. At this point they are connected to trunks leading to the proper office, where the connection is completed to the desired subscriber in the usual manner. Likewise, calls from offices M-2 and M-3 are completed over the same groups of trunks from the tandem office T to offices M-4, M-5, or M-6.

The plan described above is typical of that followed in the New York Metropolitan area for many years, the completion of the call being controlled at the tandem office by operators.

The machine switching system is not only adapted to fit into the existing tandem plan, either when used in the local central office or at the tandem office, but also makes available possibilities for considerably extending the field of usefulness of the tandem system, due to certain advantages in handling calls at tandem points by the use of machinery.

The use of a sender at the machine switching office which is capable of routing a call in any way desired permits locating the selectors which have access to the interoffice trunks at any convenient point either at the

FIG. 27—TANDEM TRUNKING PLAN SHOWING DISTANT OFFICE SELECTOR

originating office or at some distant point. In other words, the tandem office T shown on Fig. 26 may consist of a group of office selectors such as have been described previously. In this case the trunks from offices M-1, M-2 and M-3 would lead from district selectors in these offices to the office selectors at office T which would select, under control of the sender in the originating office, an idle trunk to office M-4, M-5, or M-6, as desired. At the terminating office the call would be completed through incoming and finals if it is a machine switching office, or call indicator "B" positions if it is a manual office, exactly as described previously.

If the number of points to be reached through the tandem office is greater than the capacity of a group of office selectors, a group of district selectors may be provided at the tandem office which have access to groups of office selectors located at the same office or at some distant point, as described above.

Fig. 27 shows schematically a tandem plan using the above method. Tandem office T is provided with district selectors on which terminate trunks from local offices M-1, M-2 and M-3. These selectors have

access to office selectors in the same office through which offices M-4 and M-5 are reached, and to office selectors located in the distant tandem office T-1 through which offices M-6 and M-7 are reached.

To handle calls at a machine switching tandem office originating from manual offices, operators are required at the tandem office. These operators handle calls in much the same manner as cordless "B" operators in a machine switching office, as already described. The operator receives the desired office name and number from the originating operator over a call circuit and sets it up on her keyboard, which is similar to the cordless "B" board, except that it has office keys in addition to the numerical keys. The number is received by a sender which then controls the operation of the selecting mechanism in the tandem office and other offices through which the call may pass, to the desired local office and subscriber's line.

Many different combinations of the above are possible and are employed when desired.

MAINTENANCE

As will have become apparent from the description already given there is, in the machine switching telephone central office, a large amount of apparatus which, in order to insure service of good quality, must be maintained in proper working condition. Consequently, the subject of maintenance has been very carefully kept in mind throughout the design of the system. For instance, all new pieces of apparatus used in this system have been subjected to the most rigid tests to insure that they will have a satisfactory life and that their margins of adjustment will be adequate.

When maintaining machine switching equipment, the main reliance is placed on preventive measures, so that incipient faults will be detected and corrected before they have got to the point of interfering with service. Ingenious automatic testing arrangements have been designed to aid in this preventive maintenance work. They subject the various circuits in the exchange to routine tests, and are arranged so that they will automatically test all of the circuits, one by one, under conditions more severe than they will ever be called upon to meet in service. In case some feature of any circuit has deteriorated from its normal standard of adjustment—which includes a wide margin—so that it will not meet this severe testing condition, the testing apparatus automatically stops and by supervisory lamps indicate the location of the trouble. An audible alarm is also sounded which notifies the maintenance man responsible that something requiring his attention has been found. The circuit in trouble may still be capable of giving service, but is below the standard set and may soon give service trouble if not corrected.

As applied to the sender, for example, the automatic routine test equipment picks up each sender in turn and puts it through its regular process of operation, under

conditions more severe than are encountered in practise. If the sender under test meets the operating conditions without failure, the sender is dropped and the test equipment moves to the next sender. If any trouble develops an alarm is given, which summons the maintenance man who is able to determine by the condition of the apparatus the location of potential trouble.

The operation of the testing equipment may be varied by suitable keys, so that all the features of each sender may be tested once, or so that any one feature of the sender may be tested as many times as desired.

All the equipment in the office occurs in groups, and arrangements are made for readily taking out of service for readjustment any piece of apparatus which may have been found to have potential trouble—the other members of the group continuing to handle the calls.

APPLICATION

In the preceding pages there has been briefly described a switching system which meets the exacting and complex requirements of telephone service in the largest cities and in which, so far as is practicable, the various switching operations are performed automatically. Only such operators are required in connection with this system as are necessary for handling special classes of service and certain operations in connection with the interchange of calls between manual and machine switching central offices during the transition period.

Variations in the arrangements which have been described have been developed and are available for use whenever the conditions warrant. An illustration of this is the so-called key indicator, which permits the handling of calls from manual to machine switching offices without the aid of the cordless "B" operators. This is effected by providing the operators in the manual offices with special keys and equipment for controlling directly the selection of the subscriber's line in the machine switching office.

This machine switching system marks a very important advance in a development which began shortly after the telephone was invented, and which has been most vigorously prosecuted by the engineers of the Bell System from then to the present time. Throughout this entire development period the tendency has been to introduce automatic methods and apparatus whenever they gave a better result to the public, or whenever they were attended by an economy of any kind.

How this system works has been briefly explained. What arrangements are provided for handling regular machine switching calls, calls to and from existing manual offices, private branch exchanges, etc., has been described. How the introduction of this system into a telephone network is affected will now be discussed briefly.

Obviously, the problem of introducing machine switching equipment into such an extensive and complex structure as is the telephone plant of a big city, is a large one. It is impracticable to introduce it all

at once. Its introduction must be effected gradually and this is accomplished by using it for growth and such replacements as are necessary, later extending its use as conditions warrant.

The fundamental engineering studies which have to be made and which must precede the manufacture and installation of the equipment for a machine switching office are, in all important respects, the same as those which must precede the manufacture and installation of the equipment in a new manual office. They involve a careful study of the telephone needs of the area, with a view to determining ultimately the quantities of the different kinds of arrangements necessary to give the service. This requires a study of the commercial requirements at the time when the equipment should be cut over and for several years thereafter. Data must be collected as to the probable rates of calling, the average duration of the calls and the amount of trunking to and from other offices.

With these data available, the size and arrangement of the trunk groups on the selector frames, the number, grouping and type of selectors and senders required, and the size of the power plant can be determined. From this the cabling arrangement can be worked out, and suitable floor plans prepared.

Manufacturing specifications can then be prepared in accordance with which the equipment of the office is manufactured and installed. Before the equipment is cut into service, the various arrangements are thoroughly tested individually, and when in proper condition the whole is checked up by making complete operation tests.

If time and space permitted, it would be of interest to discuss the methods of actually cutting the equipment into service, and the comprehensive program which is worked out for the training of the employees who are to handle the equipment and advising the public which is to use it. All these matters are of the utmost importance, and must be carried out systematically in order that there may be no reactions on the general service at the time of the cut-over.

Discussion

Frank B. Jewett: There is very little that I can add to what Mr. Morehouse has outlined to you in the paper except to point out one or two collateral features of this very substantial trend which we are experiencing toward the increased use of machinery to perform functions which ordinarily require human intelligence.

My principal contact with this machine switching problem has been on the engineering and manufacturing side, and the thing that has struck me most forcibly is the fact that we appear to be trying to the best of our ability to make a mechanical human being.

The register to which Mr. Morehouse refers embodies I believe, the nearest approach to human intelligence that has yet been invested in a mechanism. It has some truly remarkable characteristics which heretofore have been associated in our minds largely with the characteristics of human beings.

The attempt to go farther and farther in the direction of making inanimate material take the place of animate human beings

certain desired results, to find ways and means of effecting economies so that these results may be obtained with the lowest possible expenditure.

Regardless of the question of cost there are some cases where automatic switching equipment is useful in meeting certain definite conditions, for instance, where climatic conditions make the maintenance of an adequate operating staff almost prohibitive, or where there is a polyglot population and it becomes almost impossible to maintain an operating staff sufficiently conversant with the various languages used locally to give satisfactory service.

One of the questions that Mr. Gherardi touched upon, that of the public attitude, was very interesting to me for the reason that I had always made it a point to learn the public reaction to the service, wherever possible. I believe we, in the telephone business, have been unduly apprehensive. While the telephone business is our principal activity, it is only an incidental thing to the public. If machine switching service meets the public requirements in a more satisfactory manner than has previously been done, the reaction is favorable. If it does not, the reaction will be unfavorable. Fortunately, however, I know of no case where this reaction has been unfavorable because of the fact that the service given by machine switching telephone systems is, from many angles, superior to service given manually.

F. J. Chesterman: We in Philadelphia have very similar problems in a smaller way, to the New York problems, and we are engaged at the present moment in preparing for the Sherwood cut-over.

I think we should each of us bear in mind that in introducing developments into a telephone system such as we have in New York and in Philadelphia, it must be done in such a way as not to interfere with the orderly operation of the system. In the plan which has been adopted, with the exception of the subscriber who is directly involved and who has a dial on his own telephone, there is no change in the method of making a telephone call. In other words, whether you are calling a manual or a machine switching subscriber, the procedure is identical in either case. This seems to be the point which has bothered the layman more than any other, and in talking with a public service Commissioner recently, he had the impression that two telephones were required at the subscribers' premises, one for calling machine switching subscribers, and one for calling manual subscribers. If this were true, each subscriber would have to know the type of service which every other subscriber had, and this, in a city such as Philadelphia or Pittsburgh, is, of course, impracticable; so that one of the prime requisites of a machine switching system, which necessarily must be installed a unit at a time, is that each machine switching telephone must be able to communicate, as in the past, with the whole telephone system.

There is another requirement of machine switching, which Mr. Morehouse dwelt upon, and that is, it must be able to handle all classes of calls; not only flat and message rate, but also coin boxes. It must be able to handle calls to toll points, calls for information, and a thousand different types of calls which are encountered in the operation of a complete telephone system. Not only must the machine switching system fulfill these requirements, but it must be such a system that its use will not entail material changes in the method of operating the existing system; I refer now to the manual offices with which the machine switching system must co-ordinate.

It would be obviously a very material problem to train the manual operators to handle connections from machine switching offices in a totally dissimilar manner from that in which they handle calls from other manual offices; and Mr. Morehouse pointed out very distinctly, I think, the pronounced similarity in the method of handling calls from the two types of offices.

In a similar manner, calls from a manual to a machine switching office are handled in practically the same way that calls from

one manual office to another manual office are handled. By this means, the effect of machine switching operation is localized practically to the particular unit that we are installing, and does not interfere or change or modify in any material sense the operation of the telephone system as a whole.

I think therefore the machine switching system as described, fulfills all of the main essential requirements that we have been reviewing just now, but in addition to that, it is meeting all of the requirements for a complete telephone system.

E. B. Craft: I am simply going to touch upon some of the problems, that we have had to deal with in connection with this development, pertaining particularly to the mechanical and electrical design of the mechanism itself.

The necessity for large groups of trunks in Metropolitan areas has brought forth the necessity for large-sized selectors, and the panel mechanism which has been illustrated and described, embodies a number of features mechanically that are of general interest, not only to telephone specialists, but to any engineer who has to do with the design and construction of machinery.

Let us consider for a moment just what this mechanism has to do. We have in the selector rod that goes over the face of these panels, a piece of apparatus which is about seven feet long and weighs about a pound and a half. It must be so arranged that it can travel over the face of the terminals at the rate of possibly 60 terminals per second. As these terminals are 1-8 of an inch apart, you can gather some idea of the precision with which this rather substantial mass of material must be controlled. Of course it is not a new thing to select groups of terminals by machinery. The outstanding feature of this mechanism, however, is, that we are dealing with a much larger mass of material which must be controlled, and with much greater distance over which we must travel. This large size precludes operation by the usual forms of electro magnetic devices, and it has been necessary therefore to use continuously-applied power means. This is the reason for using the power drive.

Now, in the introduction of this power drive, we are getting into some new fields in that we must by all means insure continuity of operation. This power drive mechanism, both motors and friction roll drives which are associated with each other, must operate every hour in the day, every day in the week, and every week in the year. Such seemingly simple problems as lubrication have given a great deal of trouble. These mechanisms as I say, must operate continually, and there are real and fundamental problems of lubrication which have entered into the design of them. On the other hand, practically all parts of the mechanism, outside of the power drive itself, must operate without lubrication. Because of the lightness of the construction of some of the smaller fast-moving parts, the application of lubricating materials will oftentimes interfere with their operation, so that we have many problems where the design and the materials must be such that parts will operate for long continued periods of time without any lubrication whatever.

In this connection, it may be interesting to refer to the motor which is used to drive this selective mechanism. In order to insure this continuity of operation, there has been provided a so-called duplex motor for the operation of the lifting drives. This motor is so arranged that it normally operates directly from the usual public service supply, either alternating or direct current. In case of failure of this power supply, however, the motor is so arranged, that without any outside manipulation whatever, it automatically switches to the power leads from a storage battery located in the building, so that its continuous operation is insured. The throw-over from the main source of supply to this emergency source, is such that the motor will not stop and the mechanism is maintained in continuous operation, even though the primary source of power supply is removed.

The terminal bank which is illustrated in the paper and shown on the screen, involved some mechanical problems a little bit out of the ordinary. This rigid structure is about 39 inches

long and 15 inches high, made up of 300 strips of metal, with an equal number of insulating strips between them. This whole group of parts must be so assembled that, in its finished state, these terminals are properly centered within dimensional limits of 85/10,000 of an inch. This is done to provide as wide limits as possible in other portions of the mechanism, particularly in the moving parts. Therefore, in the fixed portions, this great precision is adhered to, to reduce to a minimum other adjustments that may have to be made.

Furthermore, these parts must be insulated from each other to withstand unusually high potentials that may occasionally be applied and in order to insure this they are tested with a potential of 500 volts. The proper insulation resistance between the parts must be maintained at a proper point at all times.

Now, in a full-sized central office, such as we have been describing, there may be as many as 4000 of these selecting mechanisms, 4000 of these rods, and in the ultimate plan for the Metropolitan area, it is expected there may be as many as 300 offices, so that we may have over a million of these devices that may be involved in the giving of service in an area such as the Metropolitan district. Each one of these selecting mechanisms must be constructed with sufficient precision that it may be removed, and a new one introduced, or so that any part of the mechanism can be replaced, without recourse to machinery for making the replacement. This presents a problem of interchangeable manufacture which is in a class by itself.

Now, we go to the dial. The only intelligence that is transmitted from the substation in this machine switching system to control the central office mechanism is through the agency of electrical impulses. Therefore, it goes without saying, that these must be very accurately controlled.

The dial which has been described to you is arranged to transmit pulses at the rate of ten per second, with a variation of plus or minus one pulse. There must be a definite relation between the period of make and break of the electric circuit so that this little device located at the substation, which is used to transmit electrical impulses, has a period of make, held between the limits of twenty-five-thousandths of a second, and fifty-thousandths of a second, and a period of break between forty-five-thousandths of a second, and one hundred thousandths of a second. What we really have here at the substation, subject to all the rough usage that devices of this sort usually receive, is a real instrument of precision.

H. P. Charlesworth: There is one matter that comes to mind which is of considerable importance from the subscriber's standpoint and which may be of interest here.

Mr. Chesterman has mentioned that one of the fundamental

requirements that a satisfactory machine switching system must meet is that any subscriber shall not be required to perform essentially different operations in reaching different switchboard systems from the same telephone. In other words, the machine switching subscriber must not have to differentiate between a manual telephone and a machine switching telephone and neither must the manual subscriber have to similarly differentiate on his part.

This naturally brings us immediately to the telephone numbering system which is referred to in the paper and perhaps just one word regarding it may be of considerable interest. The automatic system receives a call, of course, from the subscriber through the medium of the dial. The call must come in as a suitable number of electrical impulses. We would, therefore, naturally think of adopting for machine switching subscribers, telephone numbers consisting entirely of numerals, and this plan is in fact followed in small exchanges. However, in the case of New York, for example, this would mean seven numerals, three to control the selection of the desired office and four for the number itself. A letter would also have to be added if a manual party line station was being called.

Such numbers would be very difficult for both the subscriber and operators to use. Furthermore, it is obvious that it would be impracticable, in a large city, to change the form of listing of all the existing manual telephone numbers coincident with the introduction of the first machine switching office. On the other hand, it would also be undesirable to list, in the directory, machine switching subscribers entirely in numerals and manual subscribers in central office names and numerals. It will be seen, therefore, that the subscriber's numbering system to be employed in machine switching operation is an extremely important matter and in fact, for a time presented one of the most difficult problems in connection with large city operation. The solution when found, however, was extremely simple.

You will note from the photographs in the paper that by putting letters on the dial, the subscriber in dialing a letter would, in effect, be dialing a number. For example, in dialing PEN 4256, the subscriber is unconsciously dialing 736, 4256, or in other words, just what the machinery requires to complete the call. Obviously then, by simply capitalizing the first three letters of the office name and selecting satisfactory office names, which usually means the existing office names except where their first three letters conflict, it is very simple to arrange so that the subscriber can use the same form of listing for all calls. Thus the subscriber does not have to know whether the office called is a machine switching office or a manual office which, as previously stated, is the arrangement to be desired when introducing machine switching operation in large Metropolitan areas.

being carried between each pair of channels to represent the load on one crossarm. (For convenience, each complete unit of ten wires and two channels will hereinafter be referred to as a "crossarm"). The crossarms

FIG. 1—WIND TEST STRUCTURE

were spaced two feet apart vertically. Each crossarm was mounted independently of the other arms and carried on four hangers (C, Fig. 2) equipped with ball bearings at both ends, as shown at D in the same figure.

FIG. 2—ARRANGEMENT OF EQUIPMENT ON WIND TEST STRUCTURE

The motion of the crossarms was restrained by springs, attached to two opposite hangers on each arm and to the framework, and adjusted so that all wires would move as nearly as possible in parallel planes.

In order to determine the relation between wind pressure on numbers of wires carried on crossarms and a single isolated wire, a 1-1/8 in. rod, representing one wire, was mounted about five feet in front of the structure and at an elevation approximately midway between the top and bottom crossarms. This single wire was supported in the same manner as the crossarms. The hangers may be seen at L, Fig. 2, the ball bearings at M, and the restraining springs at O, the arrangement of the latter also illustrating the method of attaching restraining springs to the crossarm hangers. The single wire hangers, springs, etc., were boxed in, in order to eliminate the effect of wind pressure on the hanger arms.

The instrument employed for recording the observations is shown in Fig. 3. It will be seen that this consisted of a specially designed recorder containing six independent recording mechanisms and pens, and

FIG. 3—APPARATUS FOR RECORDING CROSSARMS AND WIRE DEFLECTIONS

six charts driven simultaneously by a single, long roller. In order to transmit the deflections of the single wire and the various crossarms to the recording meter, the Bristol electric, long distance, motion recording system was employed. This system operates on the balanced induction principle and consists of two pairs of solenoids, arranged to swing horizontally back and forth over the end of soft iron cores, and connected in parallel to an alternating current circuit. One pair of solenoids is used for transmitting and the other for receiving, any motion of the transmitting coils being followed by a corresponding movement of the receiving coils and of the recording pen.

The complete measuring apparatus thus consisted of a transmitter mounted at each end of each crossarm and of the single wire, and of the corresponding recording mechanisms and charts, the recording instrument being arranged for making simultaneous records of the deflections of the single wire and of each of the

working condition and having completed all calibrations, it was only necessary to wait for favorable weather conditions, in order to obtain the desired records. The majority of test observations and readings were made during the months of February and March, since it was found that the steadiest and highest winds occurred at that time. All equipment was frequently calibrated during this period so as to prevent any possibility of changed conditions affecting the accuracy of the final results.

In order to determine the relation between wind velocity and wind pressure on a single wire, simultaneous

FIG. 6—PRESSURE VELOCITY CURVE

observations were made, during periods of heavy wind, of the readings on the wind velocity gage and those on the chart recording the deflections of the single wire. Numerous tests were conducted in this manner and the velocities as obtained from a great number of readings, plotted against the corresponding pressures on the wire. The results thus obtained are shown by the dot and dash curve in Fig. 6, which also shows for comparison the theoretical curve plotted from the formula $P = 0.0025 V^2$, in which P is the pressure in pounds per square foot of projected area and V is the actual wind velocity in miles per hour.

In order to carry out the shielding tests, and obtain data necessary for this part of the investigation, it was only necessary to determine how the total pressure on all the wires of the structure compared with that on the single wire, during periods of high wind velocity. At the beginning of each test, all charts were carefully marked with starting points and with the name or letter of the units whose motion they were to register. The roller carrying all six charts was then set in motion and the deflections corresponding to simultaneous pressures on all units recorded.

After the completion of each test, the charts were laid out so that the deflections recorded at the same instant by the single wire and the various crossarms could be noted. Points were then chosen at suitable intervals on the single wire deflection curve and the deflections which crossarms recorded at the same instant tabulated opposite these single wire deflections. The

following table shows a sample of some of the actual test results obtained in this manner, each value of crossarm deflections being the average of numerous readings.

SAMPLE OF TEST RESULTS
(50 WIRES ON LINE)

Deflection Single Wire	Average Deflection Arm C.
7.5	6.5
12.5	9.0
17.5	12.1
22.5	15.1
27.5	19.0
32.5	23.3
37.5	26.9
42.5	31.7
47.5	35.0
52.5	39.7
57.5	44.0
62.5	49.6
67.5	53.0
87.5	72.0
92.5	78.3

Tests were made in the above manner with all five crossarms in place on the structure. Tests were also made with 40, 30, 20, and 10 wires on the line, one arm of wires being removed just previous to each series of tests, the removal of arms being in the order A, E, B, and finally D.

In order to put the data obtained from the above tests in convenient form for study, curves were plotted from the tabulated deflections, the deflections of the crossarms being plotted as ordinates and those of the single wire as abscissas.

FIG. 7—ARM C—OBSERVED DEFLECTIONS

The lower curve in Fig. 7 is plotted from the data given in the foregoing table and shows the deflections of Arm C when there was a total of 50 wires on the line. Similar curves were also plotted for each of the other arms, and in addition, a set of curves for each wire load, 40, 30, 20, and 10 respectively. The complete set of curves for arm C is shown in Fig. 7.

By applying the proper calibration curves to the deflection curves above described, it was possible to transform deflections to loads and to obtain new sets of curves showing the direct relation between forces on the several crossarms and that on the single wire. The

These values of actual comparative deflections, considered entirely without reference to calibrations for wind pressures or velocities, prove unquestionably that the deflection, and consequently the pressure, on one arm decreases as the number of wires on the line increases. In other words, they establish definitely the fact that shielding exists between crossarms.

Next considering the curves shown in Fig. 9, it is possible to gain an idea of the shielding between wires carried on the same crossarm, and also of the amount of shielding under different wind conditions. For example, when the pressure on the single wire amounted to 8 pounds per square foot, the pressure recorded on a line of ten wires was only 4.6 pounds per square foot, demonstrating that there is a very marked shielding effect between wires carried on the same crossarm, as well as between wires carried on different crossarms. Furthermore, corresponding to the pressure of 4.6 pounds per square foot on a ten-wire line, the tests showed a unit pressure of only 3.4 pounds per square foot when there were 50 wires on the line. A similar relation will be found to exist when any other unit pressure on the single wire is taken as a basis of comparison.

From the curves of Fig. 10, can be read directly the per cent of shielding which was shown by the tests to exist with various numbers of wires on the line and at different wind velocities. Thus, at a wind velocity of between 25 and 30 miles per hour, the shielding is apparently near zero, judging from the slope of the curves. In fact, the twenty-wire curve shows a zero value of shielding at a velocity of about 30 miles per hour, although the fifty-wire curve at the same velocity indicates approximately 20 per cent of shielding. The small shielding found at these comparatively high velocities is probably due to the fact that, as previously stated, it was found impracticable to adjust the recording instruments to give accurate results at low wind velocities without sacrificing accuracy in the upper ranges. It will be noted that the shielding increases with the wind velocity, varying from about zero at velocities of from 25 to 30 miles per hour to as high as 59 per cent at velocities of about 62 miles per hour, with fifty wires on the line. Furthermore, it appears that the shielding increases most rapidly between 30 and 40 miles per hour, above which the rate of increase gradually becomes less. Few observations were made at wind velocities higher than 60 miles per hour, but the curves indicate that the shielding does not increase greatly above this velocity. At an actual velocity of 57 miles per hour, which corresponds to the pressure of 8 pounds per square foot that is ordinarily assumed as the condition of heavy loading, the shielding effect varies from a minimum of about 43 per cent on a ten-wire line to approximately 57 per cent on a fifty-wire line.

In designing telegraph and telephone lines for situations of hazard, it has often been the practise in

calculating transverse loads to assume a wind pressure of 8 pounds per square foot of projected area on wires covered with ice $\frac{1}{2}$ in. in radial thickness, and then to neglect one-third of the number of wires carried—that is, to assume a shielding effect of $33\frac{1}{3}$ per cent. In the present investigation, tests show, as indicated in Fig. 10, that under a wind velocity of 57 miles per hour, which corresponds to a pressure of 8 pounds per square foot, the shielding effect varies from a minimum of about 43 per cent on a ten-wire line to approximately 57 per cent on a fifty-wire line. Evidently, therefore, the assumed shielding effect of $33\frac{1}{3}$ per cent is very conservative, since it is but 60 to 75 per cent of that shown by the tests for this velocity. It is hardly probable that the investigation contained any errors large enough to make up this difference, especially in the tests made at wind velocities exceeding 40 miles per hour.

ACCURACY OF RESULTS

While during the entire investigation of wind pressures every precaution was taken to insure the results being as accurate as possible, there still remain a number of factors whose influence should not be overlooked.

In the first place, the structure used to support the crossarms was necessarily within such distance of the wires that it may have influenced the wind currents to some extent. Furthermore, there was probably a slight "end effect" at the ends of the wooden rods where they were supported by the thin steel channel crossarms. At the most, however, this latter effect could not have altered the results by more than one per cent since the length of the span was roughly 100 times greater than the diameter of the rods.

Secondly, it was not found possible to obtain exactly similar characteristics in the several recorders nor to make the inertia of the single wire exactly proportional to the inertia of the several ten-wire units. For this reason, it was not practicable to obtain simultaneous observations of wind gusts which would be truly comparative. Although this condition was largely compensated for by oil damping, as previously described, applied to the movable wires and the recording apparatus, the actual effects were still further eliminated by working up the results only from points on the charts which were practically free from sudden changes in wind velocity. It is believed that this procedure, together with the fact that large numbers of points were averaged, practically eliminated all errors due to inertia.

Another condition which possibly influenced the results was that the steel suspension members from which the crossarms hung were not shielded from the wind. On the basis of the relatively small area these hangers presented to the wind, the error from this cause could not have exceeded one per cent and, therefore, was neglected. The hangers supporting the single wire were shielded from the wind and hence were not a source of error.

Another difference between the experimental line and a real line is that in the latter, the swaying of wires and poles causes constant variation in the position of the wires with respect to each other, while in the experimental line, the sags of the wooden rods were more constant, although not entirely uniform. While this characteristic of a real line could not, of course, be duplicated, the wires of the experimental line, nevertheless, assumed positions quite similar to those of a real line, since the natural warping of the wooden rods caused many irregularities in the sags of the different wires.

The above paragraphs discuss the principal sources of error which are known to exist. There is still another respect in which the conditions in a real open wire line could not be simulated in the experimental structure. The inertia of wires heavily loaded with ice tends to absorb much of the energy of sudden gusts of winds, before the force of the wind is finally transmitted to the supporting poles. On the other hand, the swaying of heavy wires under the influence of sudden and variable gusts of wind probably at times causes momentary forces on the supporting poles which may even exceed the direct pressure of the wind at any one instant. These conditions are obviously too complex to be duplicated in a short span line such as used in the present investigation, but their absence from the experimental line could hardly have affected the relation between the wind pressures on the single wire and the multiple wire units, which relation was the primary thing that the investigation was to determine.

It will be seen from the foregoing discussion that such inaccuracies as may have entered into the results of the tests were comparatively small. In fact, the relation between wind pressure and wind velocity was found to be approximately the same as that which other investigators have determined, the maximum difference between the experimental constant K , and the commonly accepted value, being within 8 per cent and the average difference only 3.6 per cent. It therefore seems safe to assume, for practical purposes, that the wind pressures recorded in these tests and the results deduced from them were accurate within 10 per cent.

CONCLUSIONS

The final results of the wind pressure investigation described in this paper may be summarized as follows:

1. The formula $P = 0.0025 V^2$, in which P is the pressure in pounds per square foot of projected area on cylindrical surfaces, and V is the wind velocity in miles per hour, may be used in calculating wind pressures on *unshielded* ice covered conductors.

2. A definite shielding effect exists between ice covered telegraph and telephone conductors carried on the same crossarm and closely spaced (about 12 in. center to center) as in modern telegraph and telephone practise.

3. A similar shielding effect also exists between such wires carried on different crossarms spaced two feet apart.

4. The amount of shielding on any number of wires increases with the wind velocity, and vice versa.

5. The shielding at any wind velocity varies with the number of wires, increasing as the number of wires increases, and vice versa.

6. On telegraph and telephone lines having conductors coated with ice $\frac{1}{2}$ in. in radial thickness, the total shielding effect at wind velocities corresponding to a pressure of 8 pounds per square foot, even allowing a 10 per cent reduction from the test results in order to compensate for possible inaccuracies, will run from a minimum of 39 per cent on a ten-wire line to as high as 51 per cent on a fifty-wire line.

The author desires particularly to acknowledge his obligation to Mr. R. Leedom, who personally carried out most of the work of the investigation above described, and his appreciation of the valuable assistance rendered by Mr. C. P. Siedler in the preparation of this paper.

Discussion

F. L. Rhodes: Mr. Howe's valuable paper advances our knowledge of a subject which has occupied the attention of engineering investigators for more than three hundred years. Study of the resistance of plates to the motion of fluids against them, goes back to the time of Galileo. Sir Isaac Newton, about 1687, announced the general formula based on theoretical considerations, indicating that the pressure varies with the square of the velocity, that is, $P = K V^2$.

Since Newton's time a vast amount of experimental work has been done along two lines. (1) The verification of the second degree relation. (2) The evaluation of the constant. Some investigators have added to the second degree term a small constant and sometimes first and third power terms. Fig. 6 in Mr. Howe's paper, indicating a slight tendency for the pressures at the higher velocities to exceed those computed from the second degree formula, is interesting in the light of this early work. It is now, however, generally agreed that the equation $P = K V^2$ is sufficiently precise for all practical purposes.

Much experimental work has been devoted to the evaluation of the constant in the Newtonian formula. Rouse and Smeaton in 1759, evolved a value for K of substantially 0.0050. The weight of Smeaton's reputation carried this coefficient into use far beyond conditions similar to those from which it was derived, it having been based chiefly upon experiments with windmills. Many subsequent investigators determined values for K , working with plates and solids having small surfaces borne by rotating arms which were whirled rapidly. The methods employed were subject to several sources of error.

Within the past half century more carefully conducted experiments have indicated that a constant of from 0.0040 to 0.0043 more nearly represents the actual relation than the Smeaton constant of 0.0050. These values apply to the pressure on plane surfaces normal to the direction of the wind. As early as 1798 Samuel Vince determined that the resistance offered by the convex front of a hemisphere was only about 0.4 of that offered by its flat base front. Subsequent experiments by Col. Duchemin and others showed that the resistance was much affected by the shape of the front surface. Duchemin made use of a coefficient of 0.6 to give the relation between the pressure on cylindrical surfaces as compared with the pressure on flat surfaces of the same diameter. At the present time a coefficient of about $\frac{5}{8}$ is generally used, and applying this to the constants given above for plane surfaces gives results of from 0.0025 to 0.0027, which

are closely confirmed by Mr. Howe's experimental results for a single wire.

In considering the precision of the Newtonian formula, it should not be forgotten that, strictly speaking, corrections should be made for temperature and barometric pressure. For example, the pressure decreases about 1 per cent for each $4\frac{1}{2}$ deg. Fahr. rise in temperature, and increases about 1 per cent for each 0.36 inch of barometric pressure.

Turning now to the question of shielding, Fidler, writing in 1887 on Bridge Construction, pointed out that when the wind blows upon a grating or lattice girder, the pressure on the grating or girder is somewhere between that of the entire area enclosed by its perimeter and that of the actual front surface of the bars or plates that compose it, and the pressure on a second girder in the rear of the first would usually be less than that on the first. He suggested the need of practical tests and stated that it is very probable that the amount of shelter varies somewhat with the shape and arrangement of the lattice bars, and very certain that it varies very greatly with the distance between the girders.

Quantitative results as to shielding have been conflicting. For example: Baker, in connection with the Forth Bridge Investigation between 1884 and 1890, found that if two similar disks were placed exactly in the rear of each other, but at distances apart of 1, 2, 3 and 4 diameters, the total pressure on the combination amounted respectively to 1.0; 1.4; 1.6 and 1.8 times the pressure on the front disk alone, and that the total pressure was but little if any increased by the insertion of intermediate disks. On the other hand, Thibault had found as much as 1.7 pressures at single diameter distances.

The allowance for shielding effect has apparently gradually crystallized into the use of one and one-half times the projected area of latticed structures.

It has long been known that some shielding effect occurs in the case of ice loaded wires on crossarms, and, as pointed out in Mr. Howe's paper, conservative assumptions have been made in the past to take account of this effect. It is gratifying to have available this data from actual measurements conducted on a full scale section representative of an actual wire line.

The author has called attention to a factor which is not ordinarily taken into account directly in engineering computations of wire lines, namely the inertia and the swaying of the ice loaded wires. Another factor is the swaying of the poles themselves, which sometimes, when the ground is not frozen, results in enlarging the pole hole transversely to the line, so that considerable motion of the poles and wires may result. There is also, as shown by Langley, the fact that, particularly in high winds, the air moves in a tumultuous mass, the velocity at a single fixed point sometimes jumping almost instantaneously from one extreme to the other. The variables involved in wire line engineering are many and their relations are complex. The mathematical treatment of the problems of design is of value in developing clearly the effects of changes in the various important factors involved thus acting as a guide to progress, and in smoothing out inconsistencies that would otherwise be liable to occur in the case of lines having widely different characteristics.

The final basis of the design must rest on the results of actual experience as reflected in the evaluation of the constants appearing in the mathematical relations. In this respect the author's paper contributes information of importance to all those who are interested in the design of pole lines carrying closely spaced wires.

E. C. Keenan: I am obliged to differ with Mr. Howe's conclusion that there is a shielding effect between wires, which will run from a minimum of 39 per cent on a 10-wire line to as high as 51 per cent on a 50-wire line.

On account of many failures of pole lines and wires along the railroads that I represent, which failures have seriously interfered with train operation, I have been carefully studying the question of proper strength of poles to safely carry our wires. The wind shielding effect of wires has been offered, upon several occasions,

as a reason for lessening the initial strength in the pole line structure, but, after investigation and mature deliberation, we have rejected this assumption as unwarranted by such facts as are known and the experience we have had.

My principal reason for not accepting Mr. Howe's conclusion is based upon the fact that, in my judgment, the tests with the model conducted by Mr. Howe, did not represent conditions as they actually are found in the field. The model was designed to simulate a 10-foot section of an actual pole line, the wires being represented by wooden rods $1\frac{1}{8}$ in. in diameter, so that these rods would represent a wire with a coating of ice $\frac{1}{2}$ in. thick. The model, as constructed, maintains the wooden rods, or wires, on practically an even plane. While there may have been some slight irregularity, due to the warping of the rods, it seems to me that such irregularity cannot compare with the irregularity that exists in the wires as actually maintained.

In order to determine whether or not telegraph and telephone wires are maintained so that the wires of each crossarm are on practically a horizontal plane, I had measurements taken at sixteen places along the railroad on railroad wires and wires of other companies. These tests include leads carrying from three to seven arms of wires. I give below five examples. The figures give the distances in inches of each wire from an assumed horizontal datum line.

Case No. 1—1st Crossarm—0, $2\frac{1}{2}$, $1\frac{3}{4}$, $4\frac{1}{4}$, $4\frac{1}{2}$, 5, $10\frac{1}{2}$, 6;

Case No. 2—2d Crossarm—6, $5\frac{1}{2}$, 5, $3\frac{1}{2}$, 6, 2, 1, 0;

Case No. 3—3rd Crossarm— $\frac{1}{2}$, 0, $2\frac{1}{4}$, $2\frac{3}{4}$, $5\frac{3}{8}$, $7\frac{1}{2}$, $6\frac{3}{4}$, $7\frac{1}{2}$;

Case No. 4—4th Crossarm— $3\frac{1}{2}$, $2\frac{1}{2}$, $\frac{1}{2}$, $12\frac{1}{2}$, $11\frac{1}{2}$, $2\frac{1}{2}$, $4\frac{1}{2}$, 0, 1, $2\frac{1}{2}$;

Case No. 5—5th Crossarm—5, $1\frac{1}{2}$, $7\frac{1}{2}$, 0, $1\frac{1}{2}$, 0, 10, $6\frac{1}{2}$, $9\frac{1}{2}$, $12\frac{1}{2}$.

At the other eleven places where tests were made, the results were similar to the first three cases, the last two cases being the worst found.

From these tests of the actual conditions in the field, it seems to me that very little shielding could result from wires that are, of necessity, maintained in such irregular positions.

While it may be said that the cases for which measurements are given, showing great irregularity in the sag of wires, do not represent average conditions, I desire to assure you that I have observed this condition on the ground, and I am satisfied that the sixteen tests represent the conditions that exist to a considerable extent.

The wires in Mr. Howe's model were non-flexible as compared with wires actually in service, and due to the shortness of the model span, the model wires, it seems, could not have been subject to such swaying motions as occur in actual practise in spans from 100 to 150 feet in length. Such swaying motions as occur in actual practise, undoubtedly cause the wires to deviate from the plane, thus exposing more surface to wind pressure.

In actual practise, in addition to the swaying effect, there is vibration effect, the wires doing what is commonly known in the field as "dancing," or vibrating up and down. Under these conditions the wires are very far from being on the same plane and, therefore, afford little, if any, shielding.

The supporting structure in the model does not simulate a pole support in that a pole in actual service sways considerably and, consequently, there is a general swaying effect of both poles and wires caused by gusts of wind.

The model used by Mr. Howe does not represent the actual condition of a pole line constructed on *curves* where the poles are inclined from the vertical position, and the crossarms, consequently, are not horizontal, so that the wires are not on a horizontal plane.

The above conditions seem to me to be most important, as they indicate wide variations as encountered in practise from those of the model.

In the second sentence of the first paragraph of Mr. Howe's paper, the statement is made that some observation indicates that

the pressure of the wind on lines carrying many wires, is not as great as the calculated pressure on one wire multiplied by the number of wires on the line, from which the conclusion is drawn that the reason the lines did not fail was due to the shielding effect of one conductor upon another. This, it seems to me, is a supposition, and after thoroughly investigating, it might be found that the apparent greater strength of the line was due to the conditions that were not as severe as anticipated, rather than to the shielding effect.

In the last paragraph of the first column, attention is called by Mr. Howe to the fact that the tests were made in the Jersey meadows on account of the flat and open nature of the land, permitting a free sweep of the wind, unobstructed by anything that might cause unusually heavy currents, the nearest buildings, hills and depressions in the direction from which 90 per cent of the wind blows, being at least five miles away. In this connection I should like to call attention to the observations of Dr. Humphreys, Professor of Interior, Meteorological Physics, U. S. Weather Bureau, who says:

"Near the surface of the earth the wind is always in a turmoil owing to friction and to obstacles of all kinds that interfere with the free flow of the lower layers of the atmosphere and thereby allow the next higher layers to plunge forward in irregular fits, swirls and gusts with all sorts of irregular velocities and in every direction. Indeed, the actual velocity of the wind near the surface of the earth often and abruptly varies from second to second by more than its full average value, and the greater the average velocity, the greater, in approximately the same ratio, are the irregularities or differences in the successive momentary velocities."

From the above, which is generally admitted by those who have studied the freakish and unusual action of the wind, it appears that actual conditions generally prevailing along telegraph and telephone rights of way, are more severe than in the flat, open country where the tests were made.

On page 32 of the report attention is called to the inaccuracies of the recording instruments. It would be interesting, if it were practicable to determine, the extent of these inaccuracies, because on page 25, second paragraph of the first column, the report leads me to think that it probably was considerable, as, apparently, no shielding was noticed at a velocity of 30 miles per hour, which is a rather high velocity; and then for the shielding to suddenly jump to 50 per cent at 50 miles per hour, leads me to believe that inaccuracies in the recording instruments which were noted, may have been considerably more than Mr. Howe thinks.

Attention is called to the fact that it has often been the practise in calculating transverse loads, to assume a shielding of 33⅓%. While this may have been done in certain instances, I do not believe that the practise has generally been followed by engineers, because there is not sufficient engineering basis for such assumption.

In the same column, second paragraph, "Accuracy of Results," attention is called to the effect of the structure itself upon the shielding. While the small steel channel supporting the wooden rods could have very little effect, it occurs to me that the frame itself, which is rather large and exposes quite a surface, would produce a very appreciable effect upon the wires. It would also seem that at high wind velocities if the frame happened to be rotated so as to be in the back of the supporting structure, considerable variation might be expected.

In conclusion I desire to say that, in my opinion, telegraph and telephone pole lines and wires should be constructed under the full, proper assumed loading of wind and ice for the territory in which they are located, with a factor of safety of, at least, two. Under these assumptions many variable factors must be taken into consideration, such as strengths of woods and wire, wind velocities, thickness of ice-coating, etc. The prevailing engineering, fundamental principles that have so far been followed after many years' experience, indicate that no lessening of the assumptions should be permitted unless one is absolutely sure of them, which is especially true when one considers the small

factor of safety employed in our telegraph and telephone pole line and wire work.

K. L. Wilkinson: The design of wood pole lines has always been more or less unsatisfactory from the standpoint of accuracy of calculations and the designer has had to make certain assumptions which were based on experience with overhead line construction and not on any scientifically proven physical factors. The transverse load on the line has been taken as a steady and uniform wind pressure acting equally on all wires and the pole surfaces. No allowance was made directly for impact, inertia, shielding, etc., but a rough allowance was made for these factors by using factors of safety for wood poles considerably lower than those usually assumed for wooden bridges, building and the like. Experience has shown this procedure to be justified because for many years it has been observed that certain wood pole lines stand up under storm conditions which, according to the theoretical design formulas, should cause the lines to fail. This has been widely observed particularly in telephone and telegraph lines with their large numbers of closely spaced wires and has been taken into account in their design.

The question of wind shielding, as applied to pole lines, has in the past been the subject of occasional controversy between engineers, not because its existence was doubted but because it had not been demonstrated and measured. Mr. Howe's paper is therefore particularly valuable to those interested in overhead lines construction, first because it proves that wind shielding is an important factor and second because it indicates the quantitative limits of this factor.

Shielding of one body by another in streams of fluid pressure has been a subject of consideration for many years and has been taken into account in the design of steel bridges and similar latticed structures. Experiments have been made from time to time in wind tunnels and these have yielded many valuable indications on this subject. In recent years it has been necessary to carefully study wind pressures in connection with the design of aircraft and this has yielded information which has indicated how currents of air moving at high velocities are broken up by objects of different sizes and shapes. All of these experiments and tests have tended to show that parallel objects in a stream of air do produce a certain shielding effect on each other and that this shielding depends upon the velocity of the stream of air and upon the ratio of the size of the objects to the distance between them.

I think it can therefore be said, without detracting in any way from the value of Mr. Howe's paper that he has not presented a new subject. He has, however, admirably demonstrated in a practical and scientific way the factor of wind shielding in telegraph and telephone lines and has established beyond reasonable doubt that this factor should be considered in the design of such lines.

P. J. Howe: The presentation by Mr. Rhodes of such various data relative to prior investigations of wind pressures constitutes, in effect, a comprehensive introduction to the writer's own paper on this subject. The close conformity existing between the fundamental principles previously established and the facts arrived at through the recent experiments goes far toward indicating that the design of wire carrying structures cannot have a proper engineering basis until some allowance is made for the shielding effect which closely spaced wires exert on each other.

Similarly, Mr. Wilkinson's statement, obviously based on the experience of a great telephone system, that wood pole lines stand up under storm conditions which, according to the theoretical design formulas, should cause the lines to fail, shows that there is some factor, such as shielding or the equivalent, that serves to lessen the effect of wind pressures on pole lines carrying closely spaced wires.

In his discussion of the subject on the other hand, Mr. Keenan disputes the conclusion that there is a shielding effect between wires. Unfortunately, his remarks give few engineering facts

to support the many personal opinions that are expressed and in consequence, his discussion serves principally to indicate that the presence of shielding between wires is not agreeable to the speaker. In order, however, that the Institute records may contain both sides of the various questions which have been raised, it seems desirable to make a brief answer to at least a few of the assertions made by Mr. Keenan.

In the first place, he states that the question of proper strength of poles has been carefully studied by him on account of the many failures of pole lines and wires that have occurred along the railroads which he represents and that in view of the facts obtained from such experiences, he has rejected the assumption regarding shielding. The truth of the situation is that pole lines and wires have failed many times on account of inadequate strength or maintenance, but no facts were submitted by Mr. Keenan or have ever been obtainable by the writer to show the failure from ice and wind storm of a line which theoretically ought not to have failed. The fact that lines have failed in the past is no reason whatever why shielding may or may not exist between wires.

Frequent reference is made by the speaker to the fact that the wooden rods which represented wires in the experimental structure were practically on an even plane, whereas actual wires on a pole line occupy irregular positions and vibrate up and down during high winds; also that wires on curves depart considerably from a horizontal level, due to the fact that the poles on curves are inclined from the vertical. He further asserts that wires which are very far from being on the same plane afford little if any shielding.

Whether the plane of the wires in the experimental structure was horizontal or not really makes very little difference. According to Mr. Keenan's own quotation from Dr. Humphreys of the United States Weather Bureau, the wind near the surface of the earth is in a turmoil, full of gusts, swirls and varying velocities, and hence must be considered as blowing from all directions, inclined as well as horizontal. The investigation made by the writer was made out of doors under actual out of door conditions and the results, therefore, apply to the conditions that exist during the extreme disturbances of heavy wind storms and gales. Furthermore, not only did the normal level of the test wires vary considerably, as will appear from Fig. 1 of the paper, but when subjected to the forces of 50 to 60 mile per hour gales, these wires or rods fairly danced and oscillated, much as do the wires in actual pole lines. The implication that wires must be in the same plane in order to afford shielding has little justification, in view of the findings of these experiments.

Another point made by Mr. Keenan was that, according to actual measurement, the wires on individual cross-arms vary all the way from 0 to as much as $12\frac{1}{2}$ in. from a horizontal level. These figures undoubtedly refer to very special cases of lines which are either of small importance or in need of repair. To believe that they are at all representative of actual conditions on a great railway would be a sad reflection on those who are responsible for the maintenance of the railroads' communication system. As a matter of fact, anyone who has traveled the great railroad systems of this country knows that mile after mile of the wires on the paralleling telegraph lines flash by with seldom a noticeable deviation from the uniform level of the wires carried on the various crossarms.

In commenting on the quotation from Dr. Humphreys, Mr. Keenan reaches the conclusion that conditions in the open

country where the tests were made are not as severe as those along telegraph and telephone rights of way. Just why this might be so is not evident. Certainly human experience associates the highest winds with localities where the wind has a free sweep, unimpeded and unobstructed. In any event, results of the tests are applicable to either situation since the actual wind pressures and velocities were measured and the conclusions based on these measurements.

In discussing the possible sources of error in the tests, Mr. Keenan thinks that because no shielding was noticed at velocities much below 30 miles per hour, the inaccuracies in the measuring instruments may have been more than the writer thinks. The exact accuracy or inaccuracy of the tests is, of course, indeterminable, but it must be remembered that shielding from one object to another results solely from air disturbances that extend back of the first object, and that the distance which such disturbances extend depends on the size and shape of the first object and the velocity of the wind. It is not to be expected that any shielding whatever will be experienced until the wind attains a high enough velocity for the disturbance to reach from one wire to its neighbor. This limiting velocity is shown by the curves of Fig. 10 to range between 25 and 30 miles per hour for wires of the size and spacing employed in the tests. It would undoubtedly be considerably lower, however, with larger wires or closer spacing, and higher with smaller wires or wider spacing.

Another of the writer's statements which is questioned, is "that it has often been the practise in calculating transverse loads, to assume a shielding of $33\frac{1}{3}$ per cent," Mr. Keenan stating that there is not sufficient engineering basis for such an assumption. The statement questioned said "it has often been the practise in calculating transverse loads . . . to neglect $\frac{1}{3}$ of the number of wires carried—that is, to assume a shielding effect of $33\frac{1}{2}$ per cent." This neglecting of $\frac{1}{3}$ of the wires is prescribed not only in the National Electrical Safety Code issued in 1920 by the Bureau of Standards, but also in mandatory regulations, mostly of more recent date, that have been drawn up and put into effect by the Public Utility Commissions of various states such as Ohio, North Dakota, Wisconsin, Kansas and Oklahoma. The engineering basis for the assumption that shielding exists seems to be thoroughly established, as pointed out in the discussions of both Mr. Rhodes and Mr. Wilkinson, by the long continued practise of structural engineers in allowing a considerable reduction in the theoretical area of latticed structures exposed to wind pressures. The ratio between the separation of members and their size is often much greater in latticed towers and structures than in the experimental line used in the wind tests.

One of the final points raised by Mr. Keenan is that the structure which supported the experimental pole line would produce a very appreciable effect upon the wires. This, of course, is a possibility which is difficult to appraise. The main point to keep in mind, however, is that this effect, whatever it may have been, doubtless affected all wires and, therefore, should have exerted only slight influence on the relative pressures on the different wires and the shielding of the wires, one to another.

Mr. Keenan's remaining criticisms are for the most part either immaterial or already answered in the Paper under discussion. His final remarks relative to proper strengths and factors of safety for telegraph and telephone pole line construction have no bearing whatever on the matter of shielding and need no answer.

The Wave Antenna

A New Type of Highly Directive Antenna

BY HAROLD H. BEVERAGE, CHESTER W. RICE, and EDWARD W. KELLOGG

of the Radio Corporation of America

Assoc. A. I. E. E.

Review of the Subject.—A small bungalow in a grove of oak trees just outside of Riverhead, Long Island, with a line of poles along a country road, carrying two copper wires, and ending by a stream nine miles southwest of Riverhead,—this in brief describes the Atlantic coast "ear" of the Radio Corporation of America, where the wireless messages from England, France, Germany and Norway are received, disentangled, amplified, converted into current of telephonic frequency and automatically relayed over telephone circuits to the Broad St. Office in New York, where operators take the messages by ear, or automatic recorders mark the dots and dashes on tape.

The present paper deals with the two copper wires on the line of poles, for they constitute the wave antenna which has not only marked a distinct advance in the reduction of interference and "static," but because of its aperiodic nature and effectiveness as an energy collector, has made possible the simultaneous reception of a large number of messages by one antenna, and the automatic relaying of the messages over land wires.

The use of two wires is not an essential feature of the wave antenna but permits flexibility in the location of the receiving station. In its elementary form the wave antenna consists of a straight horizontal conductor. (See Fig. 10) of the order of a wave length long, parallel to the direction of propagation of the desired signal, with the receiving circuit located at the end farthest from the sending station and with the end nearest the sending station grounded through a resistance of the proper value to practically prevent reflections. Under these conditions the desired signal waves produce comparatively feeble currents at the end nearest the sending station and strong currents at the receiver end, while disturbances coming from the opposite direction cause feeble currents at the receiver end and strong currents at the end farthest from the receiver (nearest the transmitting station) (See Fig. 2). This comparative immunity of the receiving set to disturbances coming from a direction opposite to the desired signal is lost if reflections are permitted to occur at the end farthest from the receiver. The growth of current in the direction of travel of the space wave depends on the velocity of propagation of waves on the antenna in comparison with the velocity of the space waves, the received current being strongest if the two are equal. If the characteristic wave velocity on the antenna is less than that of the space waves (or less than the velocity of light) increasing the length of the antenna increases the received current up to a certain point, after which further increase in antenna length reduces the received current. The length for maximum signal depends on the velocity ratio and wave length. The slower the antenna or the shorter the wave length received the shorter the length for maximum signal. It is very frequently the case, however, that the best directive properties are obtained with an antenna longer than that which gives the strongest signal.

The effect of the space wave is to produce in the wire a signal frequency electromotive force which affects the different parts of the antenna progressively as the space wave passes over the line. On this basis the received current can be calculated in terms of the frequency and intensity of the induced electromotive force, the direction of the space waves and the length and electrical constants of the antenna. By assuming the direction to be changed while all other

factors remain the same, and calculating the relative value of received current for various directions of signal wave, we can determine the directive properties of the antenna. The result is best shown by means of a polar directive curve. For each assumed direction for which the received current has been calculated, a radius is drawn, with length proportional to the received current. The curve drawn through the ends of these radii is known as the directive curve for the antenna. Directive curves are given (Figs. 35 to 41) which bring out the effects of antenna length, relative to the wave length, velocity of propagation, and line attenuation. The directive curves are for the most part drawn with the maximum radius taken as unit length, since this makes comparisons of directive curves easier. In general, it is found that moderate line losses are not appreciably detrimental to the directive properties of the antennas, while the fact that velocities obtainable with unloaded lines are materially below that of light, results in an actual improvement in directive properties in most cases. As a rule the longer the antenna the sharper its directive curve. While it is possible to obtain fair directive properties with antennas less than a half wave length long, this length is considered about the shortest that can be recommended.

By a process of balancing, it is possible to produce a "blind spot" or direction of zero reception, at any angle more than 90 deg. from the signal. One method of obtaining this result is by producing reflections of certain phase and intensity at the end opposite to the receiver. Reflections at the receiver end of the antenna, on the other hand, do not alter the directive properties of the antenna.

Experimental work thus far has given a qualitative check on the theory and calculations of the wave antenna, and it is hoped that further observations and measurements will shortly be made. Experimental data on wave front tilt, on which the action of the wave antenna depends, is especially meagre.

Data on wave velocity and line losses on an existing antenna can be obtained by means of a radio frequency oscillator and one or two hot-wire milliammeters. Measurements taken by the writers show much higher attenuation and lower velocities for ground return circuits than for metallic circuits. Ground resistance explains this effect. The mean depth of return currents at the longer radio wave lengths appear to be of the order of several hundred feet. The more wires in multiple in the antenna, the lower the velocity and the higher the rate of attenuation (See Fig. 66 and 68).

Reduction of atmospheric disturbances or "static", has probably received more attention from experimenters than any other one phase of radio reception. Of the various lines of attack none has been more fruitful than the employment of directive receiving systems. Every increase in directivity has resulted in an improvement in stray ratio. The wave antenna carries the principle farther than any previous type. Conditions on the eastern coast of North America are especially favorable for taking advantage of differences in direction, for the European stations are to the northeast while the predominating direction of static is from the southwest.

Various practical engineering problems in connection with the wave antenna, including its application to short wave reception, are discussed toward the close of the paper.

HISTORICAL

THE wave antenna is a long horizontal antenna and therefore belongs to the class of antennas usually referred to as ground antennas, of which it is an outgrowth.

The Wave Antenna

A New Type of Highly Directive Antenna

BY HAROLD H. BEVERAGE, CHESTER W. RICE, and EDWARD W. KELLOGG

of the Radio Corporation of America

Assoc. A. I. E. E.
of the General Electric Co.

Assoc. A. I. E. E.
of the General Electric Co.

Review of the Subject.—A small bungalow in a grove of oak trees just outside of Riverhead, Long Island, with a line of poles along a country road, carrying two copper wires, and ending by a stream nine miles southwest of Riverhead,—this in brief describes the Atlantic coast "ear" of the Radio Corporation of America, where the wireless messages from England, France, Germany and Norway are received, disentangled, amplified, converted into current of telephonic frequency and automatically relayed over telephone circuits to the Broad St. Office in New York, where operators take the messages by ear, or automatic recorders mark the dots and dashes on tape.

The present paper deals with the two copper wires on the line of poles, for they constitute the wave antenna which has not only marked a distinct advance in the reduction of interference and "static," but because of its aperiodic nature and effectiveness as an energy collector, has made possible the simultaneous reception of a large number of messages by one antenna, and the automatic relaying of the messages over land wires.

The use of two wires is not an essential feature of the wave antenna but permits flexibility in the location of the receiving station. In its elementary form the wave antenna consists of a straight horizontal conductor. (See Fig. 10) of the order of a wave length long, parallel to the direction of propagation of the desired signal, with the receiving circuit located at the end farthest from the sending station and with the end nearest the sending station grounded through a resistance of the proper value to practically prevent reflections. Under these conditions the desired signal waves produce comparatively feeble currents at the end nearest the sending station and strong currents at the receiver end, while disturbances coming from the opposite direction cause feeble currents at the receiver end and strong currents at the end farthest from the receiver (nearest the transmitting station) (See Fig. 2). This comparative immunity of the receiving set to disturbances coming from a direction opposite to the desired signal is lost if reflections are permitted to occur at the end farthest from the receiver. The growth of current in the direction of travel of the space wave depends on the velocity of propagation of waves on the antenna in comparison with the velocity of the space waves, the received current being strongest if the two are equal. If the characteristic wave velocity on the antenna is less than that of the space waves (or less than the velocity of light) increasing the length of the antenna increases the received current up to a certain point, after which further increase in antenna length reduces the received current. The length for maximum signal depends on the velocity ratio and wave length. The slower the antenna or the shorter the wave length received the shorter the length for maximum signal. It is very frequently the case, however, that the best directive properties are obtained with an antenna longer than that which gives the strongest signal.

The effect of the space wave is to produce in the wire a signal frequency electromotive force which affects the different parts of the antenna progressively as the space wave passes over the line. On this basis the received current can be calculated in terms of the frequency and intensity of the induced electromotive force, the direction of the space waves and the length and electrical constants of the antenna. By assuming the direction to be changed while all other

factors remain the same, and calculating the relative value of received current for various directions of signal wave, we can determine the directive properties of the antenna. The result is best shown by means of a polar directive curve. For each assumed direction for which the received current has been calculated, a radius is drawn, with length proportional to the received current. The curve drawn through the ends of these radii is known as the directive curve for the antenna. Directive curves are given (Figs. 35 to 41) which bring out the effects of antenna length, relative to the wave length, velocity of propagation, and line attenuation. The directive curves are for the most part drawn with the maximum radius taken as unit length, since this makes comparisons of directive curves easier. In general, it is found that moderate line losses are not appreciably detrimental to the directive properties of the antennas, while the fact that velocities obtainable with unloaded lines are materially below that of light, results in an actual improvement in directive properties in most cases. As a rule the longer the antenna the sharper its directive curve. While it is possible to obtain fair directive properties with antennas less than a half wave length long, this length is considered about the shortest that can be recommended.

By a process of balancing, it is possible to produce a "blind spot" or direction of zero reception, at any angle more than 90 deg. from the signal. One method of obtaining this result is by producing reflections of certain phase and intensity at the end opposite to the receiver. Reflections at the receiver end of the antenna, on the other hand, do not alter the directive properties of the antenna.

Experimental work thus far has given a qualitative check on the theory and calculations of the wave antenna, and it is hoped that further observations and measurements will shortly be made. Experimental data on wave front tilt, on which the action of the wave antenna depends, is especially meagre.

Data on wave velocity and line losses on an existing antenna can be obtained by means of a radio frequency oscillator and one or two hot-wire milliammeters. Measurements taken by the writers show much higher attenuation and lower velocities for ground return circuits than for metallic circuits. Ground resistance explains this effect. The mean depth of return currents at the longer radio wave lengths appear to be of the order of several hundred feet. The more wires in multiple in the antenna, the lower the velocity and the higher the rate of attenuation (See Fig. 66 and 68).

Reduction of atmospheric disturbances or "static", has probably received more attention from experimenters than any other one phase of radio reception. Of the various lines of attack none has been more fruitful than the employment of directive receiving systems. Every increase in directivity has resulted in an improvement in stray ratio. The wave antenna carries the principle farther than any previous type. Conditions on the eastern coast of North America are especially favorable for taking advantage of differences in direction, for the European stations are to the northeast while the predominating direction of static is from the southwest.

Various practical engineering problems in connection with the wave antenna, including its application to short wave reception, are discussed toward the close of the paper.

HISTORICAL

THE wave antenna is a long horizontal antenna and therefore belongs to the class of antennas usually referred to as ground antennas, of which it is an outgrowth.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 14-17, 1923.

The first work with long horizontal antennas appears to have been done in the pioneer days of radio by Marconi¹, Braun², Secher³. A short historical sketch

6 shows a photograph of part of the line. A flexible type of line construction was adopted which would make it possible to try numerous experiments such as a series of loops or series of verticals connected through a transmission line, etc. Two cross arms were provided, one at a height of 18 feet and the other 30 feet above ground. The upper arm carried two No. 10 B & S copper wires and the lower arm four similar wires. All lines were broken every ten poles, and down leads were

FIG. 7—OSCILLATION TESTS OF RIVERHEAD ANTENNA. FOUR WIRES IN MULTIPLE. $\lambda = 9400$

provided so that connections could be readily changed. The line ran seven miles approximately southwest from Riverhead along an unfrequented sand road, and was later extended to Terrell River, making a total length of nine miles. The line is as straight as it was feasible to build it, and its direction is substantially in line with the principal European long wave stations, the reception of which was a matter of primary interest.

The first tests on the new line showed that the hoped

FIG. 8—OSCILLATION TESTS OF RIVERHEAD ANTENNA. TWO UPPER WIRES IN MULTIPLE. $\lambda = 7900$

for results had been realized. Instead of an optimum length of six or seven kilometers, the signals became stronger and stronger as the receiving set was moved toward the southwest, and the signal strength there was several times greater than had been obtainable with the rubber covered antennas. While the stray ratios observed on the rubber covered antennas had seemed excellent, the new antenna fully met our expectations of improvement.

Oscillator tests on the new antenna showed that the

velocity was high and attenuation low compared with the rubber covered wires, and that it had no serious reflection points. Figs. 7, 8 and 9 show typical curves obtained with the new antenna. A comparison with similar curves, taken on the rubber covered ground wires, brings out the improved electrical properties.

The failure at the start to get good short circuit reflections when the far end of the line was grounded caused us to suspect that the high-frequency resistance of the grounds was much greater than we had estimated. These grounds were made with lines of iron wire laid in water. The substitution of copper wires removed this

FIG. 9—OSCILLATOR TESTS ON RIVERHEAD ANTENNA. SINGLE UPPER WIRE, $\lambda = 7500$. A END OPEN. B END GROUNDED THROUGH 600 OHMS.

difficulty. The adjustment of resistance for unidirectional effects was now clean cut and in accord with the theory. A dead ground at the N. E. end gave as bad a stray ratio on the average as an open circuit.

EXPLANATION OF THE ACTION OF THE WAVE ANTENNA

The wave antenna in its simplest form consists of a horizontal wire of the order of a wave length long pointing towards the transmitting station, as pictured in Fig. 10.

When the signal wave reaches the end "A" an e. m. f. is induced in the horizontal antenna wire, due to the fact that the wave front is not perpendicular to the

FIG. 10—SIMPLE FORM WAVE ANTENNA

ground, but has a tilt forward of 1 deg. to 10 deg., depending on the wave length and character of ground. Thus, at the end A, a little wave starts to run down the antenna towards the receiving station, and if it travels with the same velocity as the radio wave in space, the space wave follows right along with it, supplying energy to it as it goes and building it up, until at the end B it has reached a magnitude many times that which it had at A. This is illustrated in Fig. 11 which shows a single wave at successive time intervals. If the velocity of the wave on the wire is not equal to the space

wave (velocity of light) interference effects develop, the wave on the wire building up for a certain distance and then decreasing in amplitude. The velocities on actual antennas, however, are nearly enough equal to that of light so that for considerable lengths the wave on the wire builds up as it would on a light velocity line.

A signal coming from the opposite direction to that which we have been considering, will build up a wave on the wire in a similar way, from a small value at *B*

FIG. 11—BUILDING UP OF WAVE ON WIRE AS SPACE WAVE PROGRESSES

to a large value at *A*. If now the line were open or grounded at *A*, the wave would be reflected back over the antenna to the receiver end *B*, and would be heard. On the other hand, if we damp the end *A* in such a manner as to prevent reflections, the antenna becomes unidirectional. A non-inductive resistance, having the value $R = \sqrt{L/C}$ ohms, where *L* and *C* are the inductance and capacity of the antenna per unit length, constitutes a practically perfect damper.

FIG. 12—MECHANICAL MODEL OF WAVE ANTENNA—STATIONARY VIEW

Many mechanical analogies will occur to the reader, such as the building up of water waves in the direction of the wind. An interesting experiment is to run over thin ice. If you run at just the speed of wave propagation of the ice surface you can build up a larger wave. If you run too slow or too fast little effect is produced. To demonstrate the manner of building up of waves on a wave antenna, Rice and Kellogg built the mechanical model shown in Figs. 12 to 17. The upper line represents the space wave and the lower line the wave on the wire. Each line consists of a series of wooden sticks

strung on a pair of small steel wires a half inch apart in the case of the lower line and an inch and a half apart in the upper line. The rockers of the upper line are loaded with lead. The inertia of the rocking stick is analogous to line inductance, while the elasticity of the connection between successive sticks is analogous to the capacity between the conductors of an electrical line. The velocity can be changed by varying the tension on the wires. The dashpots at the ends practically stop reflections. The upper line provides a means of imparting energy progressively to the different portions

FIG. 13—MECHANICAL MODEL OF WAVE ANTENNA WITH END DAMPED

of the lower line, as a space wave imparts energy to the antenna line. A slight coupling between the two lines is supplied by light rubber bands stretched from short hooks on the upper sides of the lower sticks to corresponding hooks on the under side of the upper sticks. Waves are imparted to the upper line by moving one end by hand for an impulse or by a motor driven rocker for continuous waves.

Fig. 12 is a stationary view of the machine.

Fig. 13 shows a series of views taken with a moving picture camera, when an impulse is imparted to the

upper line. The growth of the wave on the lower line as it approaches the far end is readily seen. The wave on the lower line appears to pass off the end leaving the line practically stationary.

Fig. 14, compared with 13 shows the effect of removing the dashpot, thus permitting a free end reflection. We notice in these pictures a return wave which on reaching the near end, causes a movement of

FIG. 14—MECHANICAL MODEL OF WAVE ANTENNA WITH FREE-END REFLECTION

the first rocker. This illustrates the loss of unidirectional properties if the end is not damped.

Time exposures, with continuous waves of constant amplitude supplied to the upper (space wave) line, bring out the amplitudes developed on various parts of the lower line, or the equivalent of current distribution in a wave antenna.

Fig. 15 shows the increase in amplitude on the lower

line (antenna) as the waves progress from left to right. That the upper line carries practically pure traveling waves (*i. e.* has no return waves) is shown by the nearly uniform amplitude throughout its length.

Fig. 16 shows the effect of removing the dashpot at the right hand end of the lower line. Considerable movement at the extreme left end now appears, due to

FIG. 15—MECHANICAL MODEL OF WAVE ANTENNA—FULL VELOCITY, BUILDING UP

FIG. 16—MECHANICAL MODEL OF WAVE ANTENNA—FULL VELOCITY, REFLECTION AT END

FIG. 17—MECHANICAL MODEL OF WAVE ANTENNA—SLOWED DOWN

the reflected wave. The forward wave (left to right) built up on the line, is very small near the left end, so we find the amplitude there nearly uniform, as would be expected with waves traveling in one direction only (right to left). On the other hand toward the right we see very clear standing wave effects, for here the for-

ward (left to right) wave has an amplitude more nearly equal to that of the return wave.

In Fig. 17 the right hand end is again damped, and the lower line has been slowed down by reducing the tension on the wires. This illustrates the building up and down of the waves on the antenna when its velocity is much below that of the wave in space.

REDUCTION TO PRACTICAL FORM

After the construction of the Riverhead antenna, considerable time was devoted to experiments of various kinds with the new antenna, tests and comparisons of different antenna arrangements, an oscillographic study of static, and tests of station apparatus.

FIG. 18—ARRANGEMENT FOR LOCATING RECEIVING SET AT SAME END AS SURGE RESISTANCE

Messrs. Beverage, Rice, Kellogg, P. S. Carter, R. D. Greenman and E. P. Lawsing participated. A number of practical developments were evolved in the course of this work.

The "Reflection Transformer" Circuit. In order that the receiving set might be located at the same end of the line as the surge impedance, thereby facilitating adjustment, the arrangement shown in Fig. 18 was proposed by Kellogg. The two wires work in multiple as an antenna, but act as a balanced transmission line to bring the signal currents back from the southwest end. This scheme obviates the use of extra wires for the return transmission line and thus avoids the problem of preventing detrimental effects of nearby conductors.

FIG. 19—FIRST BALANCING CIRCUIT EMPLOYED FOR OBTAINING ZERO RECEPTION FROM THE BACK END

When the primary of the "reflection transformer" was opened the receiving set was quiet, showing that the transmission line although it was not transposed, was not introducing any undesirable electromotive forces. Thus a horizontal loop receives neither static or signal.

Compensation for Back Wave. Beverage showed that while the resistance could be adjusted to give a minimum for static while listening to European signals, still better stray ratios were obtained by combining with the signal currents brought in over the transmission line, a small amount of the currents flowing to ground at the northeast end of the antenna. This he accomplished

with a phase adjuster and intensity coupler of the type used by Mr. Alexanderson in the barrage receiver. The circuit arrangement is shown in Fig. 19.

The two long wave stations New Brunswick (13,600 meters) and Annapolis (16,900 meters) were of great assistance in making tests and adjustments. Either station could be entirely put out by using the phase and intensity adjustments of Fig. 19. It was found that when the adjustments were made for putting New Brunswick out, the stray ratio was best on the European stations whose wave lengths were near that of New Brunswick, and that when Annapolis was put out the adjustments were such as to give the best possible stray ratio for the longer wave European stations. In other words, the best stray ratio was obtained when the end conditions were adjusted to put out the image of the desired European station. If a light-velocity wave antenna is an exact number of half wave lengths long, the mathematical analysis shows that it is unidirectional provided the true surge impedance is connected between antenna and ground at the end nearest the transmitting station. This is illustrated in Fig. 29. Whether the true surge impedance is non-inductive or contains a capacity or inductive component will depend upon the

FIG. 20—METHOD OF BALANCING BACK END CURRENTS BY REFLECTIONS FROM DAMPED END

characteristics of antenna and ground at the frequency under consideration. Kellogg pointed out that since the antenna was not an exact number of half wave lengths long, the back wave effect would prevent the antenna from being unidirectional even though the true surge impedance had been used, and it was for this reason that Beverage found that balances were required to obtain the best stray ratio. Another method proposed by Kellogg of supplying this necessary compensation was to insert a circuit consisting of inductance, resistance, and capacity in series in the neutral at the end nearest the transmitting station, as shown in Fig. 20. By adjusting the resistance and varying the capacity through the point where it tuned out the reactance of the coil, a wave of any desired intensity and phase could be reflected down the antenna to exactly compensate for the back wave effect and thus render the antenna unidirectional.

If only one station is to be received the circuit shown in Fig. 20 is as satisfactory as any that the writers have found. For reception of long wave stations an antenna output transformer was used having a step-down ratio of 200 to 10 turns, and having a complete iron magnetic circuit of about 3/4 square inch cross section, made of

0.0015 enamelled sheet iron of the kind developed for the Alexanderson alternators. The secondary was connected in series with the first tuned circuit of the receiving set.

FIG. 21—MULTIPLEX RECEIVING SYSTEM

Multiplex Reception. The simultaneous reception of a number of stations was one of the next objects of our work. If the surge impedance is set at the best value for a mean wave length, and no finer adjustment of the

The arrangement shown in Fig. 21 was worked out, and proved entirely satisfactory. Each coupling tube feeds a receiving set, and the antenna output transformer and artificial line, with its sliding contacts and potentiometers, serve to impress the desired potentials on the grids of the tubes. Since the load is negligible there is no reaction between the different sets. Grounded shields between the secondaries of the antenna output transformer prevent electrostatic reactions. The desired component of the currents or potentials in the ground circuit can be obtained in any desired phase by moving the sliding contact along the artificial line, and in the needed intensity by adjusting the potentiometer. The artificial line has a characteristic impedance of about 400 ohms and reflections are prevented by a resistance of about this value. This results in a phase adjustment which gives practically constant intensity. Five thousand ohms potentiometers are used, and these constitute so small a load on the artificial line that the adjustment of any one does not appreciably alter the potential distribution on the line. The artificial line, damped as it is at the far end, acts as a practically pure resistance in the antenna surge impedance circuit. By

FIG. 22—WAVE ANTENNA CIRCUITS. PRESENT ARRANGEMENT

back-end compensation is attempted, then it is only necessary to provide more secondaries for the antenna output transformer, Fig. 20. In order that one set should not sap too much energy from another, transformers were designed with very slight reaction between the secondaries. Some data were taken of the best resistance and reactance in the ground circuit, as a function of wave length, and networks were figured out which would give the desired impedances at the wave lengths of the stations which it was most important to receive. This system of multiplexing, however, did not appeal to the writers as the most satisfactory solution of the problem. A system was wanted in which all the adjustments for each station to be received could be made without reacting on the adjustments for the others.

adjustment of the series and shunt resistance boxes the antenna damping resistance may be set at the best average value, leaving only a small residual to be "cleaned up" by the artificial line adjustments.

Fig. 22 is a more detailed diagram showing some changes which have been made since the original installation.

Shielded Sets. The aperiodic nature of the wave antenna and the success of the coupling tube multiplex system made it clear that there would be call for operating a number of receiving sets in the same building. The artificial line and antenna output transformer had been designed for operating four sets, but this was not necessarily the limit. In fact, later, when the new Riverhead station was laid out a total capacity of nine

receiving sets was planned, six of which are now in daily operation. The amplifiers, detectors, and tuners previously used in the receiving sets of the Radio Corporation were unshielded, and the practise had been, where two sets were in use in the same station, to keep them well separated and operate from separate batteries. To meet the new situation, a new line of apparatus was developed. Each piece of apparatus was in a metal lined box, the metal lining being grounded, and connections between the boxes were made through shielded cable. All tuned inductances consisted of astatic pairs of coils, of compact form, thus reducing chances of magnetic coupling. The radio amplifier was shielded between stages as well as externally. The amplifiers and detector have individual plate and filament filters in the supply lines. A two stage filter was introduced in the circuit between the detector and the audio amplifier in order to prevent radio frequency currents and potentials from getting into the audio circuits where they might cause back coupling or interference between sets. Low resistance telephones were used to minimize electrostatic coupling. These pre-

FIG. 23—RECEIVING STATION, RIVERHEAD, LONG ISLAND

cautions made it possible to operate the several sets in close proximity, and from the same plate and filament batteries, without any interference between sets, and to employ high radio and audio amplification without trouble from back coupling.

It was usual in receiving the high power European stations to develop a high-frequency potential of about 7 volts at the plate of the last tube in the radio amplifier, with a useful current of about 0.2 milliamperes. By connecting the output of the audio amplifier to a good telephone line, satisfactory tone signals were received and copied in New York City. Beverage arranged a rectifier for the audio frequency currents and operated a telegraph sounder, obtaining very satisfactory signals in this way when static was moderate or light. During the spring of 1921, considerable commercial traffic was received directly in New York in this manner, using the private telegraph wire which connected the Riverhead experimental station with the Broad St. Office of the Radio Corporation. One demonstration which aroused considerable interest consisted in putting Carnarvon's

signal on the telegraph line at Riverhead, and automatically repeating it at New York into the New Brunswick control line, so that the operators in the British station heard their own signal coming back on New Brunswick's wave.

When the success of the wave antenna had been demonstrated at Riverhead similar antennas were constructed at Chatham, Mass. and Belmar, N.J. where the Radio Corporation was already operating receiving stations. These new antennas gave satisfactory per-

FIG. 24—ANTENNA PANEL, RIVERHEAD RECEIVING STATION

FIG. 25—SHIELDED RECEIVING SETS, RIVERHEAD, LONG ISLAND

formance in commercial service until the long wave traffic was finally concentrated in the new Riverhead station which the Radio Corporation constructed during the summer of 1921. Fig. 23 shows the present Riverhead Station. Fig. 24 shows an output transformer, artificial line and potentiometers, Fig. 25 shows shelves with two receiving sets. The building does not provide space for operators, since all signals are transferred to telephone lines and copied directly by operators

in the New York Office, or recorded automatically on tape.

THEORY¹⁰

In order to work out a formula by which the directive properties of a wave antenna can be calculated, we shall consider space waves of some specified frequency, since the directive properties of a given antenna depend on the wave length to be received.

Case 1. Signal Direction Parallel to Antenna, Zero Loss Antenna. As the space wave travels along over the antenna, it induces an electromotive force successively in the different portions of the line. We may represent the electromotive force at the end A of the antenna shown in Fig. 26 by

$$e_a = E_0 \sin \omega t \quad (1)$$

volts per kilometer

FIG. 26—MEASUREMENTS REFERRED TO IN DERIVATION OF EQUATIONS

Since it takes x/v seconds for the space wave traveling with a velocity v to reach the point X, the electromotive force e_x in the wire at the point X will be behind e_a in phase, or

$$e_x = E_0 \sin \omega (t - x/v) \quad (2)$$

Let us confine our attention for the present to the effects of the electromotive force induced in a small section of the wire dx kilometers in length, and situated x kilometers from the end A. Since e_x is expressed in volts per kilometer, the voltage induced in dx kilometers of wire will be

$$e_x dx \text{ or } E_0 dx \sin \omega (t - x/v)$$

FIG. 27—CURRENTS RESULTING FROM VOLTAGE INDUCED IN SMALL SECTION OF ANTENNA

We may think of this little section of line as an alternator Fig. 27, supplying current to two transmission lines in series, one running to A and the other running to B. A line damped at the far end, so as to prevent reflections, shows an impedance $Z = \sqrt{L/C}$ ¹¹ ohms at the input end, whatever the length of the line. We have here assumed such damping. If each line has an impedance Z ohms the alternator must work through an impedance $2Z$ and will produce a current at X,

10. The Mathematical work of this paper is due to Kellogg.

11. This expression for Surge Impedance is strictly correct only for zero loss lines, but at radio frequencies it is a very close approximation for ordinary lines.

$$di_x = \frac{e_x dx}{2Z} = \frac{E_0 dx}{2Z} \sin \omega (t - x/v) \quad (3)$$

The alternator at X in forcing the current di_x through the line, gives rise to a train of waves moving toward B and another train of waves moving toward A. The resulting currents at the ends of the line di_{bx} and di_{ax} will be retarded in phase, as compared with di_x . If u is the velocity of wave propagation along the wire,

it will take $\frac{l-x}{u}$ seconds for the forward waves to reach B, and x/u seconds for the backward waves to reach A.

$$\text{Then } di_{bx} = \frac{E_0 dx}{2Z} \sin \omega \left(t - x/v - \frac{l-x}{u} \right) \quad (4)$$

$$di_{ax} = \frac{E_0 dx}{2Z} \sin \omega (t - x/v - x/u) \quad (5)$$

The total current at the end of the line is the sum of

FIG. 28—DETERMINATION OF CURRENTS AT END OF WAVE ANTENNA BY VECTOR DIAGRAMS

the currents produced by each of the sections dx long in the line. We may perform the summation by integrating equation (4) or (5) between the limits $x = 0$ and $x = l$, or by means of a vector diagram as shown in Fig. 28. The current at the end of the line di_{bx} or di_{ax} , resulting from the induced electromotive force in a section dx long, situated x kilometers from A, has a

maximum cyclic value or vector length $\frac{E_0 dx}{2Z}$ and a

phase angle which varies with x , as shown in expression (4) and (5). Hence the summation will consist in

adding a series of vectors, each $\frac{E_0 dx}{2Z}$ long, and each at its proper phase angle. Taking the phase of e_a for reference, the angle of lag of di_{bx} as shown in (4) is

$$\psi_{bx} = \omega \left(\frac{x}{v} + \frac{l-x}{u} \right)$$

These expressions give $I_b = 112$ microamperes and $I_a = 12.2$ microamperes for the problem worked graphically in Fig. 28. The difference between these values and those found from the graphical solution is due to the inaccuracy involved in the graphical method using so few sections.

It will be noticed that if the sign of n is changed in (11) we get (12). We may consider the sign of the signal velocity v , to be negative when the signal comes from the opposite direction. Since n is defined as u/v , this would give n a negative sign. Therefore, there is only one formula required, and to find the back end current I_a we consider the signal direction to be reversed.

We showed that if $u = v$ the arc is a straight line and $I_a = \frac{E_0 l}{2Z}$. If we set $n = 1$ in (11), we get the indeterminate form $0/0$, and to evaluate the expression we make use of the relation that $\frac{\sin a}{a}$ approaches 1 as a approaches 0, where the angle a is expressed in radians. Thus in (11)

$$\frac{\sin \frac{1}{2} \beta l (1 - n)}{\beta (1 - n)}$$

which may be written

$$\frac{\frac{1}{2} l \sin \frac{1}{2} \beta l (1 - n)}{\frac{1}{2} \beta l (1 - n)}$$

approaches $\frac{1}{2} l$ as $\frac{1}{2} \beta l (1 - n)$ approaches 0, and expression (11) takes the value

$$I_b = E_0/Z \times \frac{1}{2} l \text{ or } \frac{E_0 l}{2Z}$$

Hence when $u = v$

$$I_b = \frac{E_0 l}{2Z} \quad (11a)$$

Figure 29¹⁴ shows the receiver end and back end currents calculated by equations (11a) and (12) for antennas of various lengths, assuming

$$\begin{aligned} u &= v = 3 \times 10^5 \text{ kilometers per second} \\ \lambda &= 12 \text{ kilometers} \\ E_0 &= 0.010 \text{ volts per kilometers} \\ Z &= 500 \text{ ohms} \end{aligned}$$

These curves bring out the unidirectional properties of the wave antenna.

Case II. Signal at an Angle to Antenna, Zero Loss Antenna. So far we have considered only signal waves traveling in the direction of the antenna. To calculate the directive properties of the antenna, we must find the

14. This figure is practically a reproduction of a curve plotted by Mr. P. S. Carter, based on his calculations previously mentioned.

effect of a signal of the same wave length and intensity coming at an angle to the antenna. In the first place there will be a difference in the electromotive force E_0 induced in a unit length of wire. In Fig. 30A, we imagine ourselves looking down at two horizontal wires, each of unit length, situated in the midst of a signal wave whose magnetic lines are shown as dotted lines in the figure. Only the magnetic lines in a very thin layer

FIG. 29—RELATIVE CURRENTS AT THE TWO ENDS OF A WAVE ANTENNA

immediately over the plane of the wires are shown. These magnetic lines have a horizontal movement indicated by the arrow, and a downward movement resulting from the forward tilt of the wave front. The horizontal movement causes no cutting of the conductor. Owing to the downward movement, the wires will be cut by all of the lines which cross them in the figure. The numbers of magnetic lines which cross wires No. 1 and

FIG. 30—EFFECT OF ANTENNA ANGLE ON INDUCED ELECTROMOTIVE FORCE PER UNIT LENGTH

No. 2 are in the ratio 1 to $\cos \theta$, and the induced electromotive force per unit length will be in the same ratio. Another point of view is illustrated in Fig. 30B, in which we imagine ourselves as looking at the ends of the magnetic lines, which now appear as dots. Here the same two wires are shown, and the actual direction of motion of the magnetic lines is indicated. Only

those lines within the region a will cut wire No. 2 which appears in this projection as $A' - B'$, while all those in region b will cut No. 1, and the ratio of a to b is again $\cos \theta$. We shall therefore multiply by $\cos \theta$ to take account of the difference in induced electromotive force. That is to say if a signal coming in the direction of the antenna induces E_0 volts per kilometer, a signal of the same intensity coming from an angle θ to the antenna will induce $E_0 \cos \theta$ volts per kilometer.

The angle which the signal direction makes with the antenna also effects the time required for the wave front to pass over the antenna, and therefore affects the relative phases of the electromotive forces induced in the different parts of the antenna. From the time the maximum electromotive force occurs at A to the time the same thing occurs at X the wave has only to travel a distance $x \cos \theta$ as indicated in Fig. 31, and this will

require $\frac{x \cos \theta}{v}$ seconds, where v is the velocity of the

signal wave. If the induced electromotive force at A is $e_a = (E_0 \cos \theta) \sin \omega t$ then at X it will be

$$e_x = (E_0 \cos \theta) \sin \omega \left(t - \frac{x \cos \theta}{v} \right) \quad (13)$$

Comparing (13) with (2) we see that we now have the factor $\frac{v}{\cos \theta}$ where we had simply v , and where we had

E_0 we now have $E_0 \cos \theta$. Replacing v by $\frac{v}{\cos \theta}$ mean

changing u/v or n to $n \cos \theta$. Making these changes in (11) gives us, for the current due to a signal coming from a direction θ from the antenna.

$$I_\theta = \frac{E_0 \cos \theta}{Z \beta (1 - n \cos \theta)} \sin \frac{1}{2} \theta l (1 - n \cos \theta) \quad (14)$$

FIG. 31—EFFECT OF SIGNAL ANGLE ON TIME REQUIRED FOR WAVE TO TRAVERSE ANTENNA

If the signal is traveling in the direction of the antenna, $\theta = 0$, and $\cos \theta = 1$, and (14) becomes the same as (11). If the signal is from the opposite direction $\theta = 180$ deg., $\cos \theta = -1$ and (14) becomes the same as (12).

Let us apply formula (14) to the calculation of the directive curve of the antenna whose currents for $\theta = 0$ and $\theta = 180$ deg. were determined in Fig. 28. The calculations are shown in Table I. Column IX,

multiplied by E_0/Z would give the currents corresponding to the value assumed for E_0 . To show directive properties, however, it is more satisfactory to give the current for any direction in terms of its ratio to the current which the same signal would produce if it came from the direction for which the antenna gives maximum reception. Thus column X gives the relative current strengths as found by dividing all the figures of column IX by the largest figure in the column which is 5.6 and corresponds to $\theta = 0$. Fig. 32 shows the directive

FIG. 32—DIRECTIVE CURVE OF WAVE ANTENNA. $\lambda = 15$ KM.
 $l = 12$ KM., $\alpha = .0$, $u = 0.8 v$

curve of the antenna, obtained by plotting the relative currents as shown in column X radially at the corresponding angles.

Case III. Line Losses Considered. The factor *line attenuation* has so far been left out of account in order to simplify the problem. We assumed that the current at the end of the line, resulting from a wave which started at some point X , had the same strength as at X , although of different phase.

In the case of bare copper wire on poles, the errors due to ignoring line losses are not in general large enough to give misleading results. There are many instances however in which line losses are high or the antenna unusually long, where these effects cannot be neglected.

When there are no reflections to cause standing wave effects, the decrease in current strength as we go farther from the source is expressed by the relation $I_x = I_0 e^{-\alpha x}$, in which I_0 is the current strength at the source, I_x the current at a distance x from the source, and α is the "attenuation constant" of the line. A value of 0.05 per kilometer for α , means that the current decreases about 5 per cent with every kilometer which the wave travels.

In deriving equations (4) and (5), we regarded the

TABLE I

The waves from X to A travel x kilometers on the wire, and are reduced in intensity in the ratio $e^{-\alpha x}$ and retarded in phase by $\omega x/v$ or βx radians. Therefore

$$\begin{aligned} d i_{ax} &= d i_x e^{-\alpha x} e^{-j \beta x} \\ &= d i_x e^{-(\alpha + j \beta) x} \\ &= \left\{ \frac{E_0 d x \cos \theta}{2 Z} e^{-j \omega x (\cos \theta)/v} \right\} e^{-(\alpha + j \beta) x} \\ &= \frac{E_0 d x \cos \theta}{2 Z} e^{-(\alpha + j \beta + j \omega x (\cos \theta)/v)} \end{aligned} \quad (21)$$

The total current I_b is the sum of all the currents $d i_{bx}$, corresponding to all values of X , or in other words we integrate the expression (20) for $d i_{bx}$ between the limits $x = 0$ and $x = l$.

$$I_b = \frac{E_0 \cos \theta}{2 Z} e^{-(\alpha + j \beta) l} \int_0^l e^{(\alpha + j \beta - j \omega x (\cos \theta)/v)} dx$$

Performing the integration and substituting the limits gives

$$I_b = \frac{E_0 \cos \theta e^{-(\alpha + j \beta) l} \{ e^{(\alpha + j \beta - j \omega l (\cos \theta)/v)} - 1 \}}{2 Z \left(\alpha + j \beta - j \omega \frac{\cos \theta}{v} \right)}$$

This expression gives the value of I_b , but it is more convenient for calculation if several changes are made in its form.

Putting $e^{-(\alpha + j \beta) l}$ inside the parenthesis gives

$$I_b = \frac{E_0 \cos \theta \{ e^{-j \omega l (\cos \theta)/v} - e^{-(\alpha + j \beta) l} \}}{2 Z \left(\alpha + j \beta - j \omega \frac{\cos \theta}{v} \right)}$$

Taking $e^{-j \omega l (\cos \theta)/v}$ out of the parenthesis gives

$$I_b = \frac{E_0 \cos \theta e^{-j \omega l (\cos \theta)/v} \{ 1 - e^{-(\alpha + j \beta - j \omega l (\cos \theta)/v)} \}}{2 Z \left(\alpha + j \beta - j \omega \frac{\cos \theta}{v} \right)}$$

Since $\omega/v = \frac{\omega n}{v} = \beta n$, we may substitute

$j \beta (1 - n \cos \theta)$ for $j \beta - j \frac{\omega \cos \theta}{v}$, giving

$$I_b = \frac{E_0 \cos \theta e^{-j \omega l (\cos \theta)/v} \{ 1 - e^{-\{ \alpha + j \beta (1 - n \cos \theta) \} l} \}}{2 Z [\alpha + j \beta (1 - n \cos \theta)]} \quad (22)$$

A more satisfactory form of the equation for purposes of calculation is obtained by separating the attenuation and phase angle factors in the expression

$e^{-\{ \alpha + j \beta (1 - n \cos \theta) \} l}$ and substituting $\frac{2 \pi}{\lambda}$ for ω/v

and $\frac{2 \pi}{n \lambda}$ for β

This gives

$$I_b = \frac{E_0 \cos \theta e^{-j(2 \pi l/\lambda) \cos \theta} \{ 1 - e^{-\alpha l} e^{-j \frac{2 \pi}{n \lambda} l (1 - n \cos \theta)} \}}{2 Z \left[\alpha + j \frac{2 \pi}{n \lambda} (1 - n \cos \theta) \right]} \quad (22a)$$

This is the complete expression for the current at the end B farthest from the signal source.

The total current at A is found similarly by integrating expression (21) for $d i_{ax}$ between the limits $x = 0$, and $x = l$

$$\begin{aligned} I_a &= \frac{E_0 \cos \theta}{2 Z} \int_0^l e^{-(\alpha + j \beta + j \omega x (\cos \theta)/v)} dx \\ &= - \frac{E_0 \cos \theta \{ e^{-[\alpha + j \beta + j \omega l (\cos \theta)/v]} - 1 \}}{2 Z \left[\alpha + j \beta + j \frac{\omega \cos \theta}{v} \right]} \end{aligned}$$

Substituting $j \beta (1 + n \cos \theta)$ for $j \beta + j \frac{\omega \cos \theta}{v}$ and

putting the $-$ sign in the parenthesis, we have

$$I_a = \frac{E_0 \cos \theta \{ 1 - e^{-\{ \alpha + j \beta (1 + n \cos \theta) \} l} \}}{2 Z [\alpha + j \beta (1 + n \cos \theta)]} \quad (23)$$

or

$$I_a = \frac{E_0 \cos \theta \{ 1 - e^{-\alpha l} e^{-j \frac{2 \pi}{n \lambda} l (1 + n \cos \theta)} \}}{2 Z \left[\alpha + j \frac{2 \pi}{n \lambda} (1 + n \cos \theta) \right]} \quad (23a)$$

Discussion of Equations. Equations (22) and (23) give the currents at the two ends of the antenna in their relative magnitude and phase relations with respect to the induced voltage per kilometer E_a , at the end A of the antenna. The assumptions throughout are that the antenna is straight and uniform and free from reflections at the ends, and that the signal wave causes no other electromotive forces in the circuit than that in the horizontal wire. The assumption that the induced electromotive force per unit length of conductor is the same in all parts of the antenna, and is independent of the amplitude of the wave on the wire, means that the reduction in intensity of the space wave by divergence or ground absorption has been neglected, and that no saturation effect has been considered. The absorption and divergence of the space wave may be estimated with fair approximation, and in most cases with antennas of moderate length, will be found to be negligible. No evidence of saturation has so far come to the writers' attention. In cases where the antenna has exceeded the length which gave maximum signal, the limit to the amplitude of the waves on the wire, has been set by the velocity difference or the line losses.

It will be noticed that (22) is the same as (23) except that the algebraic sign before the term $\cos \theta$ is reversed, and the factor $e^{-j \omega l (\cos \theta)/v}$ appears in the numerator of (22). The latter term has no effect on magnitude

purpose of the directive curve is to show the relative receiver currents for different signal directions, the factor $\frac{E_0}{2Z}$ which is the same for all directions, is

omitted (or in other words assumed to have a value of 1) and the relative currents shown in column XI. are ob-

FIG. 36—DIRECTIVE CURRENT OF IDEAL WAVE ANTENNA, ONE WAVE LENGTH LONG. $\alpha = 0$, $n = 1$, $l = 12$, $\lambda = 12$

tained by dividing all the calculated currents of column X by the largest one of those, which corresponds to $\theta = 0$. The corresponding directive curve is shown in Fig. 35.

FIG. 37—DIRECTIVE CURVE OF WAVE ANTENNA ONE HALF WAVE LENGTH LONG. $\lambda = 12$ KM., $l = 6$ KM., $\alpha = 0.05$, $u = 0.8v$

FIG. 38—DIRECTIVE CURVE OF WAVE ANTENNA TWO WAVE LENGTHS LONG. $\lambda = 12$ KM., $l = 24$ KM., $\alpha = 0.05$, $u = 0.8v$

served for long waves (7000 to 25,000 meters) on bare 0.102 inch (0.259 cm.) diameter copper wire supported on poles. Fig. 36 shows the directive curve for an antenna one wave length long on the assumption of zero attenuation and light velocity. By analogy with transmission line practise, we have referred to a wave

$\cos \theta^\circ$ degrees. The graphical method of finding the magnitude and phase of this vector difference is shown in Fig. 42. Here the unit vector of zero phase angle OA is drawn horizontally to the right. The vector OB is then drawn with the length $e^{-\alpha l}$ and phase angle $-\frac{360^\circ l}{n\lambda} (1 - n \cos \theta^\circ)$. Then BA is the

vector difference sought. Its magnitude is determined by measuring the length BA and its phase angle by extending OA and BA and measuring the angle between them.

The magnitude of the denominator is

$$\sqrt{\alpha^2 + \left[\frac{2\pi}{n\lambda} (1 - n \cos \theta) \right]^2}$$

and its phase angle $\tan^{-1} \frac{\frac{2\pi}{n\lambda} (1 - n \cos \theta)}{\alpha}$.

FIG. 42—CHART FOR DETERMINING MAGNITUDE AND PHASE OF

$$\left\{ 1 - e^{-\alpha l} e^{-j \frac{2\pi}{n\lambda} l (1 - n \cos \theta)} \right\}$$

We have now determined the magnitude and phase angles of the quantities in the numerator and denominator of the expression for I_b .

The magnitude of I_b is obtained by performing the arithmetical operations of multiplication and division using the absolute values of the vector quantities.

The phase angle of I_b is found by adding together the phase angles of the two vectors occurring as a product in the numerator and subtracting the phase angle of the vector in the denominator.

As an example let us find the magnitude and phase of the current I_b for an antenna of the following characteristics:

- Wave length $\lambda = 12$ kilometers
- Antenna length $l = 12$ kilometers
- Attenuation constant $\alpha = 0.05$ per kilometer
- Space wave velocity $v = 3 \times 10^5$ kilometer per second
- Antenna wave velocity $u = 2.4 \times 10^5$ kilometers per second

Ratio $n = u/v = 0.8$ (numeric)

Ratio $\frac{E_0}{2Z}$ assumed = 1 ampere per kilometer

Angle at which signal strikes antenna = θ degrees

If we substitute the above values in equation (22a) using the form (absolute magnitude) / Phase angle, to designate a vector quantity, we obtain

$$I_b = \frac{\{1 / -360^\circ \cos \theta\} \{1 / 0^\circ - 0.55 / -450^\circ (1 - 0.8 \cos \theta)\} \cos \theta}{\sqrt{(0.05)^2 + [0.654(1 - 0.8 \cos \theta)]^2} / \tan^{-1}(0.654(1 - 0.8 \cos \theta) / 0.05)}$$

If we substitute various values of θ in this equation, we obtain the magnitude and phase of I_b as given in Table III. The calculation of magnitudes is taken from Table II, since the constants assumed are the same in the two cases.

Equation (23) or (23a) is the vector equation which determines the magnitude of I_a and its phase relation with respect to the reference vector E_a . Equation (23a) is

$$I_a = \frac{E_0 \cos \theta \{1 - e^{-\alpha l} e^{-j \frac{2\pi}{n\lambda} l (1 + n \cos \theta)}\}}{2Z \left[\alpha + j \frac{2\pi}{n\lambda} (1 + n \cos \theta) \right]} \quad (23a)$$

If we substitute the assumed numerical values we obtain

$$I_a = \frac{\{1 - 0.55 / -450^\circ (1 + 0.8 \cos \theta)\} \cos \theta}{\sqrt{(0.05)^2 + [0.654(1 + 0.8 \cos \theta)]^2} / \tan^{-1}(0.654(1 + 0.8 \cos \theta) / 0.05)}$$

If we substitute the various values of θ in this equation, we obtain the magnitude and phase angle of the current I_a given in Table IV.

Compensation of Back End Currents. An example of a problem which requires the calculation of both the magnitude and phase of the end currents is the determination of the directive curve of an antenna in which the current due to waves coming from a particular "back end" direction is "balanced out" by means of some of the current from the other end of the antenna.

Let us imagine there is an intense source of disturbance directly behind the antenna whose directive curve is given in Fig. 35, and for which we have just calculated the magnitude and phase of I_b and I_a , and that we wish to neutralize the effect of this disturbance by an adjustment of the damping circuit at A.

From equation (22) or Table III we have for $\theta = 180$ deg., $I_b = -0.968 / +301$ deg.

From equation (23) or Table IV we have for $\theta = 180$ deg., $I_a = -8.15 / -40$ deg.

A fraction of I_a is to be reflected in such phase that it will cancel I_b in the receiver.

The current in receiver at B is $I_b = -0.968 / +301$ deg.

The required compensating current at B is $I_{cb} = -0.968 / +301 \text{ deg.} - 180 = -0.968 / +121 \text{ deg.}$

We have taken the compensating current as one half cycle or 180 deg. behind I_b in phase.

To allow for attenuation, and the time required for propagation from A to B , we must produce by the reflection at A , a current

$$I_{ca} = \frac{-0.968}{e^{-\alpha l}} / +121^\circ + 450^\circ = -1.76 / +571^\circ$$

The 450 deg. is the angle corresponding to the time of propagation or $360^\circ \frac{l}{m \lambda}$

Thus at A we have -40 deg. and with compensation, a

This represent We cannot re reflection point, which such a phase advance implies.

A current, however, which is two complete cycles behind the desired value; that is, to say a current $-1.76 / + 571 \text{ deg.} - 720 \text{ deg.}$ or $-1.76 / - 149 \text{ deg.}$ will give cancellation of all but the first two waves of the train, and this current which is 109 deg. behind I_a can be obtained by reflection. Experience has shown that in spite of the failure to neutralize the first two waves in a train, a very high degree of balance is obtainable, both on signals and static.

The terminal impedance required to give a specified reflection, may be determined from the vector relation

$$Z_t = Z \frac{I_1 - I_2}{I_1 + I_2} = Z \frac{1 - I_2/I_1}{1 + I_2/I_1} \quad (25)^{15}$$

in which Z_t is the terminal impedance, Z the surge impedance of the line, I_1 the current due to the oncoming wave and I_2 the current due to the reflected wave. In the present case I_1 is I_a and I_2 is the desired $-1.76 / - 149 \text{ deg.}$

Then

$$I_2/I_1 = \frac{-1.76 / - 149^\circ}{-8.15 / - 40^\circ} = 0.216 / - 109^\circ$$

$$= -0.070 - 0.204j$$

$$1 - I_2/I_1 = 1.070 + 0.204j$$

$$1 + I_2/I_1 = 0.930 - 0.204j$$

$$\frac{1 - I_2/I_1}{1 + I_2/I_1} = \frac{1.070 + 0.204j}{0.930 - 0.204j} = 1.055 + 0.450j$$

Substituting this value in (25) we have

$$Z_t = Z (1.055 + 0.450j)$$

If the line surge impedance Z is 500 ohms, (with zero phase angle) the terminal impedance to give the desired neutralization would be 500 $(1.055 + 0.450j)$ or 527 ohms of non-inductive resistance and 225 ohms of inductive reactance.

Placing this impedance in the ground circuit at A will cause a similar reflection of all waves of the same length reaching A , whether due to a signal in line with the antenna or to a disturbance coming from a different direction. That is to say the reflected wave will in each case be 0.216 of the magnitude of the oncoming wave, and 109 deg. behind it in phase. When the reflected wave reaches the end B , its amplitude will be reduced to $0.55 \times 0.216 = 0.119$ of that of I_a and its phase will be further retarded by 450 deg. giving a total lag of 559 deg. behind I_a . Thus to find the directive curve of the antenna with the impedance described at A , we calculate I_a by equation (22), for each value of $\theta \text{ deg.}$, determining the phase angle of I_a as well as its magnitude, multiply its magnitude by 0.119, retard its phase by 559 deg. and find the resultant when it is added vectorially to I_b , calculated by formula (23) for the same value of $\theta \text{ deg.}$

Fig. 43 shows the relations between I_b , I_a and the reflected current, for $\theta = 180 \text{ deg.}$

In Table V we have given the calculations for the

15. See page for derivation.

directive curve of the compensated antenna. The magnitudes and phase angles of I_a and I_b are taken from Tables III and IV. Instead, however, of rotating $0.119 I_a$ backward by 559 deg. and adding it vectorially to I_b , we have rotated it 180 deg. less, and subtracted it vertically from I_b , which is an easier operation to perform and gives the same result. This backward rotation of 379 deg. , is, for the purpose of finding the vector difference, equivalent to one of $(379 \text{ deg.} - 360 \text{ deg.}) = 19 \text{ deg.}$ The table shows the values of $0.119 I_a$, rotated backward 19 deg. , and the vector difference found by subtracting this from the corresponding I_b . Thus to find the directive curve of any compensated antenna, we first choose the direction for which we wish to have zero reception. Then we compare I_a and I_b for this value of $\theta \text{ deg.}$ and determine the factor by which I_a must be multiplied and the angle through which it must be rotated to make it coincide with I_b . Then for each other value of $\theta \text{ deg.}$ we multiply I_a by the same ratio and rotate it through the same angle, and subtract the vector so found, vectorially from I_b .

Inspection of the table shows that in the example we have worked out, the effect of the reflection on the

FIG. 43—VECTOR RELATIONS IN COMPENSATION PROBLEM

receiver current is negligible for values of θ less than 90 deg. Therefore, the front end of the directive curve is not appreciably altered or the reception of the desired signal affected by the reflection we have been considering.

Fig. 44 shows the directive curve plotted from the calculations given above. This is for the same antenna and same conditions as Fig. 35, except that the "reflection balance" has been applied to give zero reception from the back.

In the case of an antenna producing relatively large back end currents, as, for example, a quarter wave length antenna, the front end of the directive curve would be considerably affected by a reflection designed to produce zero back end reception.

Effect of Reflection at Receiver End. The effect of reflection at the receiver end of the antenna may be shown as follows:

Let I_b = Wave built up on wire by signal at end B
(Equation 22)

From (26) the total current in the receiver is

$$I_R = I_b (1 + b) = \frac{1 + b}{1 - c d} (I_b + c I_a) \quad (30)$$

When there was no reflection at B we had a receiver current

$$I_R = I_b + c I_a$$

We now have a receiver current in which I_b and I_a are combined in exactly the same manner, but their

resultant is multiplied by the factor $\frac{1 + b}{1 - c d}$, which

being a function of line length and terminal conditions only, and not a function of I_a , I_b , or signal direction θ deg. does not alter the directive properties of the antenna.

The relation shown in (30) is strictly true only for steady state conditions. Let us illustrate what occurs when a train of waves first reaches the antenna. To take a simple case we may assume $I_a = 0$, so that (30)

becomes $I_R = I_b \frac{1 + b}{1 - c d}$ as the ultimate current.

When the first wave I_b reaches B and is reflected the total current at B is

$$I_b (1 + b)$$

The reflected wave reaches A with a value $d I_b$, is reflected back and reaches B with a value $c d I_b$ giving a total wave $I_b (1 + c d)$ which by reflection at B produces a receiver current $(1 + b) I_b (1 + c d)$.

After a second double reflection the total oncoming wave at B is made up of the wave I_b reaching the receiver for the first time, a wave $c d I_b$ which has been reflected down the line and back, and a wave $c^2 d^2 I_b$ which has been down the line and back twice. The total oncoming wave $I_b (1 + c d + c^2 d^2)$ by reflection at B produces a receiver current

$$(1 + b) I_b (1 + c d + c^2 d^2)$$

After a large number of reflections the receiver current is

$$(1 + b) I_b (1 + c d + c^2 d^2 + c^3 d^3 + c^4 d^4 + \dots) \\ = (1 + b) I_b \frac{1}{1 - c d} = I_b \frac{1 + b}{1 - c d} \text{ as given by (30)}$$

If the reflection coefficient at either A or B is small (which is generally true) or if the line attenuation is high, $c d$ will be small and the steady state value of receiver current is approached very quickly.

Let us apply equation 30 to the case of the compensated 12 kilometer antenna whose directive curve is shown in Fig. 44. Here in order to give zero reception for $\theta = 180$ deg., we produced a reflection at A such as to give a current at B whose magnitude is 0.119 of that of I_a and whose phase is 559 deg. behind I_a . Hence

$$c = 0.119 e^{j(-559^\circ/57.3^\circ)}$$

Suppose that instead of the surge impedance at the

receiver end, we have a transformer having 400 ohms inductive reactance and 100 ohms effective resistance. Taking the surge impedance of the antenna as 500 ohms (non inductive) the reflection coefficient at B will be

$$b = \frac{1 - Z_i/Z}{1 + Z_i/Z} = \frac{1 - (0.2 + 0.8j)}{1 + (0.2 + 0.8j)} \\ = \frac{0.8 - 0.8j}{1.2 + 0.8j} = 0.12 - 0.6j \\ = 0.612 e^{j(-79^\circ/57.3^\circ)}$$

$$\text{Since } e^{-(\alpha + j\beta)l} = 0.55 e^{j(-450^\circ/57.3^\circ)} \\ d = b e^{-(\alpha + j\beta)l} = 0.336 e^{j(-529^\circ/57.3^\circ)}$$

and

$$c d = 0.04 e^{j(-1088^\circ/57.3^\circ)} = 0.04 (\cos 1088^\circ + j \sin 1088^\circ) = 0.0396 - 0.0056j$$

$$\frac{1 + b}{1 - c d} = \frac{1.12 - 0.6j}{0.9604 + 0.0056j} = 1.163 - 0.63j \\ = 1.323 e^{j(-28.5^\circ/57.3^\circ)}$$

FIG. 45—VECTOR RELATIONS IN DOUBLE REFLECTION PROBLEM.

Without reflection at B , the receiver current of the compensated antenna, as shown in Column XVII of Table V was $I_b + c I_a$ or $I_b + I_a \times 0.119 e^{j(-559^\circ/57.3^\circ)}$

With the reflections caused by the receiver circuit we have just been considering the current in the transformer primary will be

$$1.323 e^{j(-28.5^\circ/57.3^\circ)} (I_b + I_a \times 0.119 e^{j(-559^\circ/57.3^\circ)})$$

or a current of 32.3 per cent greater for each value of θ than that given in column XVII of Table V. The directive curve or relative current for different values of θ is the same as before. Fig. 45 shows the vector relations of the currents at the ends of the line, for the

signal direction $\theta = 120$ deg. Both I_b and I_a as given by formulas (22) and (23) have negative signs, and the negative signs are retained throughout rather than reversing the vectors in the diagrams, which would somewhat obscure the angular relations. If the entire diagram is turned 180 deg. (looked at up side down) the vectors appear in their true positions.

Short Antennas. The question of the possibility of obtaining in less space directive properties approaching those of a full wave length antenna is of considerable

FIG. 47— $l = 3$, $\lambda = 12$, $\alpha = 0.5$, $n = 0.8$

interest. Fig. 47 shows the directive curve of a quarter wave antenna without compensation. It is obvious that so long as there is considerable inequality in the size of the two lobes of a figure-eight directive curve such as Fig. 47, a back end zero can be obtained by compensation without entirely sacrificing the signal, or front end reception, but how favorable a total directive curve would result is not apparent until detailed calculations are made.

Among the first experiments tried on the Riverhead antenna was loading to give various propagation velocities. It was pointed out at that time by Rice that reducing the velocity on a full wave length antenna to something less than the velocity of light would result in a sharper directive curve, but tests showed that the natural velocity of the line was so nearly equal to the best velocity that there was little to be gained by loading. The urgent problem at the time was to obtain the best possible reception of European signals, utilizing as much space as seemed conducive to this result. Tests had shown the half wave antenna, with back end compensation, to be definitely inferior to the full wave length antenna. The question of short antennas was therefore not investigated until some months later when the principal engineering problems connected with

multiplex reception with the wave antenna had been worked out.

At the suggestion of Mr. R. H. Ranger, of the Radio Corporation, calculations were made by Kellogg of the directive properties of short antennas on which the velocity had been reduced by loading to the best value for the wave length and antenna length in question. Mr. Ranger reasoned that since reducing the velocity sharpened the directive curve of a full wave length antenna, it might be possible, by sufficiently reducing the velocity, to compensate for reduced length and perhaps obtain a good directive curve in very small space. The most favorable velocity was found to be that which gave zero (or minimum) reception at the back end, without compensation. The condition for this is that

$$v/u = \lambda/l - 1$$

in which l is the length of the antenna

v is the velocity of light

u is the antenna velocity

λ is the wave length

Figs. 48 and 49 show directive curves for quarter and eighth wave length antennas with velocities equal to one third and one seventh of that of light respectively in accordance with the above equation.

FIG. 48—DIRECTIVE CURVE OF SLOWED DOWN QUARTER WAVE LENGTH ANTENNA $\alpha = 0.5$, $n = 0.333$, $l = 3$, $\lambda = 12$

By way of comparison, the directive curves Figs. 50 and 51 have been calculated for compensated antennas without loading. The back end areas of these curves are seen to be slightly greater.

Multiplex reception with different compensation for each wave length is possible with the unloaded, compensated antennas. On the other hand, with the slowed down antenna, the velocity is right only for one wave length. In order to receive other wave lengths, compensation would be employed in addition to the loading.

Fig. 52 shows the directive curve for an 18 kilometer wave length of the slowed down antenna, whose directive curve for $\lambda = 12$ kilometers is shown in Fig. 48. The dotted line *A* shows the directive properties without compensation and the solid line *B* is the directive curve with compensation. Fig. 53 shows the directive curve for the same antenna receiving an eight

Compared with the simple unloaded, compensated antenna, the slowed down antenna has a better directive curve at one wave length, but a narrower range of satisfactory multiplex reception. The signal strength

FIG. 49—DIRECTIVE CURVE OF SLOWED DOWN EIGHTH WAVE LENGTH ANTENNA. $\alpha = 0.5$, $n = 0.143$, $l = 1.5$, $\lambda = 12$

FIG. 50—DIRECTIVE CURVE OF NORMAL VELOCITY QUARTER WAVE LENGTH ANTENNA, COMPENSATED. $l = 3$, $\lambda = 12$, $\alpha = 0.5$, $n = 0.8$

kilometer wave. We observe that the slowed down antenna can be multiplexed by compensation and receive longer waves than that for which its velocity is adjusted, but that for shorter waves it is unfavorable.

FIG. 51— $l = 1.5$, $\lambda = 12$, $\alpha = 0.5$, $n = 0.8$

FIG. 52—A UNCOMPENSATED. B COMPENSATED. $l = 3$ KM., $\lambda = 18$, $\alpha = .05$, $n = 0.333$

is of the same order of magnitude on both—considerably less than on an uncompensated full velocity antenna of the same length. The intensity factor or receiver

current per unit value of the quantity $\frac{E_0}{2Z}$ in equation (22), is shown in Table VI for the short antennas whose directive curves are given in Figs. 47 to 53. The

X to obtain the directive curve. The difference is especially marked in the case of a half wave length antenna with signals coming at right angles to the antenna. If the half wave length wave antenna were acting like a series of static antennas the reception for $\theta = 90$ deg. would be about half of the full intensity or half that for $\theta = 0$. On the other hand if the wave antenna depends on wave front tilt the reception from 90 deg. to the antenna would be zero for all lengths. As a test of this the Belmar wave antenna was cut at a point about 5.8 kilometers from the station, giving a short antenna, with the 200 kw. New Brunswick sending station ($\lambda = 13,600$ meters) on the side. The reception of New Brunswick, only 50 miles away, was of the same order of intensity as European stations, thus indicating that the half wave antenna was substantially dead on the side.

When the new antenna at Riverhead was completed, it afforded an opportunity to test a long loop, as a receiving circuit. The two top wires which were 9 meters above ground were connected through from Riverhead to Terrell River or the full length of the antenna, and two of the lower wires which were about $5\frac{1}{2}$ meters above ground, were similarly connected through. The upper and lower wires were connected together through a damping resistance at Riverhead (the north-east end), and the receiving set was connected between the upper and lower wires at Terrell River. European signals were extremely weak on this loop, as compared with intensity obtained when the receiving set was connected from either pair or wires to ground. In the latter case there appeared to be no choice between the upper and lower wires.

In other words there is no differential effect due to the difference in height of the wires. The effect of height was again tested at Schenectady using a wave length of 120 meters and a wire one wave length long at heights ranging from 0.8 meters to 2.9 meters. The received current was found to be practically independent of the height. This is what would be expected from an antenna which works by virtue of the forward tilt of the wave front. If the currents in the antenna were due to the space potential of the wire above ground the received current would be proportional to the height of the wire.

There is another conclusion which follows from the theory that the action of the wave antenna depends upon the tilt of the wave front. Low, wet ground, or salt marsh would be an unfavorable location so far as signal intensity is concerned. No experimental evidence on this point has come to the writers' attention. Before conclusions can be drawn from tests or comparisons it is necessary to make sure that conditions are the same in other respects. In one instance with which the writers are familiar, two antennas, in locations several miles apart were constructed parallel and as much alike as possible. One followed a small stream and the other was over comparatively dry ground. The two antennas gave substantially equal signal intensities. Presum-

ably in this case the low resistance ground was too restricted and local to have any appreciable effect on the tilt of the twelve to fourteen kilometer waves on which the observations were made. For ground of a given resistance the wave front tilt increases as the wave length decreases, and for short waves (less than 1000 meters) there is a substantial tilt, sufficient for satisfactory operation even over wet ground.

Zenneck¹⁷ has worked out equations for the forward tilt of the wave front as a function of wave length, and the specific resistance and dielectric constant of the soil. The tilt is expressed as the ratio of the horizontal to the vertical potential gradient of the space wave.

In its general form Zenneck's formula is

$$X/Z = \sqrt{\frac{g + j \omega c}{g' + j \omega c'}} \quad (31)$$

in which

X is the horizontal potential gradient of the space wave

Z is the vertical potential gradient of the space wave

g is the leakage conductance between parallel faces of a centimeter cube of air

g' is the leakage conductance between parallel faces of a centimeter cube of ground

c is the capacity between parallel faces of a centimeter cube of air

c' is the capacity between parallel faces of a centimeter cube of ground

For all practical purposes the conductance g for air is zero, so that the formula becomes

$$X/Z = \sqrt{\frac{j \omega c}{g' + j \omega c'}} \quad (32)$$

Expressed in electrostatic units

$$g' = \frac{9 \times 10^{11}}{\rho}$$

$$c = \frac{1}{4 \pi}$$

$$c' = \frac{K}{4 \pi}$$

in which ρ is the specific resistance of the earth in ohms for a centimeter cube, and K is the dielectric constant of the earth. Average values of ρ and K as given in Fleming¹⁸ are shown in Table VII.

18. Principles of Electric Wave Telegraphy and Telephony by J. A. Fleming, Third Edition P. 800.

Fig. 55 shows the values of X/Z for various values of wave length λ , specific resistance ρ and dielectric constant K . With long waves and low-resistance soils $\omega c'$ is negligible compared with g' , in which case

$$X/Z = \sqrt{\frac{j \omega c}{g'}} \quad (33)$$

This is a function of wave length and specific resistance, and is shown in the sloping lines of Fig. 55. On the other hand if the waves are so short and the soil resistance so high that g' is negligible compared with $\omega c'$ we have

$$\mathbf{X}/\mathbf{Z} = \sqrt{C/C'} = \sqrt{1/K} \quad (34)$$

which is independent of wave length or soil conductivity and is shown for several values of K in the horizontal lines at the top of the figure. To find the value of X/Z for a certain wave length and a soil of a given resistivity and dielectric constant we use whichever curve (the sloping line of equation (33) or the horizontal line of equation (34) gives the lower value for X/Z . If near the intersection of the two straight lines we use the

FIG. 55—WAVE FRONT TILT, X/Z BY ZENNECK'S FORMULA

transition curve which is shown dotted. To illustrate, if $\lambda = 1000$ meters and $K = 4$, we find

$X/Z = 1.3 \div 10$ for $\rho = 1 \times 10^5$
 $2.5 \div 10$ for $\rho = 4 \times 10^5$
 $3.9 \div 10$ for $\rho = 1 \times 10^6$ (on transition curve)
 $4.9 \div 10$ for $\rho = 4 \times 10^6$ or greater. (On horizontal line for $K = 4$).

It will be noted that in Zenneck's formula (32), the ratio X/Z is a vector quantity whose phase angle ranges from 0 deg. to 45 deg. By far the most common condition is that g' greatly exceeds $\omega c'$ (*i. e.* the earth carries current by conduction rather than by capacity) in which case the phase angle is nearly 45 deg. The phase difference means that the vertical and horizontal potential gradients do not become zero simultaneously, but the electric field is a rotating one. Under these circumstances if a straight conductor is held in various positions in a vertical plane parallel to the direction of wave propagation, there will be no direction of the con-

ductor in which the electromotive force induced in it is zero. This may account for the doubtful results obtained in attempts to measure wave tilt by observing the angle of zero or minimum electromotive force in a straight conductor rotated in a vertical plane parallel to the signal direction. Wherever the tilt is considerable so that it might be readily measured, the minimum is correspondingly dull.

More satisfactory as a test of the theoretical conclusions, would be quantitative measurements of the relative magnitudes of the electromotive forces induced in horizontal and vertical conductors, for various wave lengths and ground conductivities. Determination of the phase relations would provide a further check.

An observation of relative signal intensities on a large loop and a wave antenna, indicated a wave tilt of the order of magnitude called for by Zenneck's formula, but little data of this kind have been taken. The large values of horizontal voltage gradient found in the measurements mentioned below by Beverage and Weinberger were at first considered greater than could be accounted for by wave tilt. Assuming probable values of ground resistance, the ratio of horizontal to vertical potential gradient according to Zenneck's formula is of the order of magnitude of one or two per cent, whereas the measured horizontal gradient was about 30 per cent of the vertical gradient calculated by Austin's formula. The space potential theory of action however is still less capable of accounting for the potentials observed. If we assume ground water to be 100 feet (30 meters) below the surface of the ground, and the earth above ground water level to have a specific resistance of 2×10^6 ohms per centimeter cube, which is about the value found by measurement, we find for a 15,000 meter wave length that the potential difference between ground water and surface would be less than that corresponding to a difference of elevation of two feet in the space above ground. Considering the ground as constant potential, and expressing the vertical potential gradient as $G e^{-j(2\pi x/\lambda)}$ (in which $e^{-j(2\pi x/\lambda)}$ expresses the change of phase with distance x measured in direction of propagation) the potential of the wire at a height h with respect to ground would be $h G e^{-j(2\pi x/\lambda)}$ and the potential

gradient along the wire would be $\frac{d}{dx} h G e^{-j(2\pi x/\lambda)}$

$$= -j \frac{2\pi}{\lambda} h G e^{-j(2\pi x/\lambda)}. \quad \text{If the height of the}$$

wire is 10 meters and the wave length 15,000 meters the magnitude of the horizontal potential gradient would be

$$\frac{2\pi h}{\lambda} G = \frac{2\pi \times 10}{15.000} G = 0.0042 G \text{ or } 0$$

of the vertical gradient, which is
formula gives for the horizontal
due to wave tilt. Theoretical

over, that there is no electromotive force induced in a horizontal wire over a perfectly conducting earth, and therefore the space potential picture of operation is untenable.

Experimental Directive Curve. Fig. 56 shows a directive curve obtained experimentally. A transmitting set was operated, supplying about 5 kilowatts to a small vertical antenna, at 120 meters wave length. On a field about 600 meters from the transmitting station a system of wave antennas was erected consisting of twenty-four lines each 55 meters long and about one meter above ground, radiating from a central point like the spokes of a wheel. By joining two opposite spokes together at the center, a wave antenna was obtained 110 meters long. Using the next pair gave a similar antenna 15 deg. from the last. A ground of about 20 ohms resistance was provided at each end of

Fig. 56— $l = 110$, $\lambda = 120$

each antenna. The current at one end of the antenna was measured with a thermocouple and galvanometer, the opposite end being damped by a resistance. Measurements were taken successively on the several antennas, while the radiation was kept as nearly constant as possible. From the series of readings thus obtained Fig. 56 was plotted.

A number of factors was present to cause a difference between the shape of the experimental directive curve Fig. 56 and the curve A of Fig. 57 calculated by equation (22). The resistance used at the end opposite the ammeter was not the true surge impedance of the line, as determined by later measurements. The end verticals were high enough in comparison with the length of the antenna to cause currents of considerable relative magnitude, the ground was not perfectly level, and the divergence of the waves was appreciable on

account of the nearness of the sending station. Additional observations had been planned, but the work was interrupted before another directive curve could be obtained. As it stands the directive curve shown in Fig. 56 serves as a qualitative check on the theory.

During the same series of short wave tests, readings were taken to show the building up of the current in an antenna. A wire sectionalized every ten meters was used in the antenna which pointed toward the trans-

FIG. 57—CALCULATED DIRECTIVE CURVES FOR 120 METER ANTENNA. A—SIMPLE WAVE ANTENNA. B—CORRECTED FOR REFLECTIONS AND END EFFECTS. $l = 0.12$, $\lambda = 0.13$, $\alpha = 2.0$, $n = 0.865$.

FIG. 58—OBSERVED CURRENT DISTRIBUTION IN 120 METER ANTENNA

mitting station. The line was broken successively at the sectionalizing points and the current read with the thermocouple and galvanometer. The values of current are plotted in Fig. 58. Humps such as appear in the curve might be due in part to imperfect damping, but such humps are to be expected from the theory. The total current at any point X in the antenna Fig. 26 is the resultant of the forward wave built up on the part of the antenna between A and X, and the back wave from the part between X and B.

circuited. The frequencies at which the maxima and minima occur indicate the line velocity, while the ratio of minimum to maximum impedance gives a basis for calculating the attenuation.

Determination of Constants from Input Impedance. Fig. 61 shows a generator (or oscillator) supplying alternating current to a line. This results in waves which travel from A to B. Assuming for the time being that there is no reflection at B and no return waves, the relation of voltage to current is $E/I = Z$ in which Z is the surge impedance of the line. When the generator makes the point A positive with respect to ground it supplies a current in the direction A — B. Let us now imagine the generator and the absorbing terminal circuit interchanged so that the generator supplies current to the end B and the waves travel from B to A. The impedance measured at the terminals of the generator will be the same as before, but when the line is positive with respect to ground the current will be flowing in the direction B — A. Therefore if we define the voltage as positive when the line is positive with respect to ground, and the current as positive when in the direction A — B, then for waves traveling in the direction A — B the voltage is $E = +Z I$, but for waves traveling in the direction B — A the relation is $E = -Z I$.

If the forward wave leaves the end A with a magnitude and phase represented by I_0 it will reach B with the magnitude and phase $I_0 e^{-(\alpha + j\beta)l}$ or $I_0 e^{-\gamma l}$ in which $\gamma = \alpha + j\beta$. We shall represent the forward wave as it reaches B by the symbol I_1 . Then since $I_1 = I_0 e^{-\gamma l}$, $I_0 = I_1 / e^{-\gamma l} = I_1 e^{\gamma l}$. Likewise at any point X, Fig. 61, x kilometers from B measured toward A, the current of the forward wave is $I_1 e^{\gamma x}$. And the voltage of the forward wave at X is $Z I_1 e^{\gamma x}$.

If the reflected wave leaves B with a magnitude and phase represented by I_2 , it will be $I_2 e^{-\gamma x}$ when it reaches X, and $I_2 e^{-\gamma l}$ when it reaches A. And the voltage of the return wave is $-Z I_2$ at B, $-Z I_2 e^{-\gamma x}$ at X and $-Z I_2 e^{-\gamma l}$ at A.

When waves traveling in both directions are present, the total current in the line at any point X will be the vector sum of the currents due to the two trains of waves or

$$I_x = I_1 e^{\gamma x} + I_2 e^{-\gamma x} \quad (36)$$

And the total voltage will be the vector sum of the voltages $Z I_1 e^{\gamma x}$ and $-Z I_2 e^{-\gamma x}$, or

$$E_x = Z I_1 e^{\gamma x} - Z I_2 e^{-\gamma x} \quad (37)$$

The ratio of voltage to current, or the impedance at X is

$$E_x/I_x = Z \frac{I_1 e^{\gamma x} - I_2 e^{-\gamma x}}{I_1 e^{\gamma x} + I_2 e^{-\gamma x}} \quad (38)$$

or at A the impedance is

$$Z_A = Z \frac{I_1 e^{\gamma l} - I_2 e^{-\gamma l}}{I_1 e^{\gamma l} + I_2 e^{-\gamma l}} \quad (39)$$

This becomes equal to Z if $I_2 = 0$, and becomes $-Z$ if $I_1 = 0$. The negative sign means that power is being supplied from the line to the terminal circuit by waves which travel in the direction B — A, instead of from the terminal circuit to the line as is the case for waves leaving A. If the waves leaving A are larger than those arriving at A (i. e. if $I_1 e^{\gamma l} > I_2 e^{-\gamma l}$) there is a net power supply to the line.

If the line is made very short Z_A , the impedance at A, of the line plus the terminal circuit, must eventually become equal to that of the terminal circuit alone or equal to Z_t . Setting $l = 0$ in (39) and equating to Z_t , we have

$$Z_A \text{ (for } l = 0) = Z \frac{I_1 - I_2}{I_1 + I_2} = Z_t \quad (40)$$

The value of Z_t relative to Z determines the relation of the reflected wave I_2 to the oncoming wave I_1 at the reflection point B. From (40)

$$\frac{I_1 - I_2}{I_1 + I_2} = Z_t/Z \quad (41)$$

Adding 1 to each side of this equation,

$$\frac{2 I_1}{I_1 + I_2} = 1 + Z_t/Z \quad (42)$$

Subtracting 1 from each side of (41)

$$\frac{-2 I_2}{I_1 + I_2} = Z_t/Z - 1 \text{ or } \frac{2 I_2}{I_1 + I_2} = 1 - Z_t/Z \quad (43)$$

From 42 and 43

$$I_2/I_1 = \frac{1 - Z_t/Z}{1 + Z_t/Z} \quad (44)$$

This is the general vector expression for reflection, which was given on page 56, where an illustrative problem was worked. We have used the term "reflection coefficient" for the ratio I_2/I_1 .

If the line is short circuited at the end, $Z_t = 0$ and (44) becomes $I_2/I_1 = 1$ or $I_2 = I_1$. The total current $I_1 + I_2$ then becomes $2 I_1$ which is the familiar case of the current doubling at a short-circuit reflection.

If $Z_t = Z$, $I_2/I_1 = 0$, or $I_2 = 0$ or there is no reflection.

With an open circuit at the end $Z_t = \infty$, I_2/I_1 becomes -1 , or $I_2 = -I_1$, the total current at the reflection point being $I_1 + I_2 = I_1 - I_1 = 0$. The total voltage at the reflection point becomes $Z(I_1 - I_2) = Z(I_1 + I_1) = 2 Z I_1$ or twice that due to the oncoming wave alone. This is the case of doubling of voltage at an open circuit reflection.

Fig. 62 shows the current and voltage vectors at 0, 1, 2, 3, 4, 5 and 6 kilometers from a short-circuit reflection, the attenuation constant being taken as 0.05 per kilometer, the wave length 15 kilometers and the velocity ratio $n = 0.8$ so that the length of a wave on the wire is 12 kilometers. Since in the case of a short circuit reflection $I_2 = I_1$, their vectors coincide at the reflection point. The vector $I_1 e^{\gamma x}$ of the forward wave, is advanced in phase and increased in magnitude as we proceed toward the source, or away

from the reflection point, while the vector of the reflected wave, $I_2 e^{-\gamma x}$, becomes smaller and retarded in phase. At 3 kilometers from the reflection end, the current vectors have rotated 90 deg. each, in opposite directions, and are therefore 180 deg. apart, and the resultant current is seen to have a minimum value equal to the difference in the lengths of the two vectors. Referring next to the voltage diagram, the vectors $Z I_1$ and $-Z I_2$ at the reflection point are equal and opposite giving zero resultant, for there is no voltage across the line at the short circuit. At 3 kilo-

FIG. 62A—CURRENTS AT VARIOUS DISTANCES FROM SHORT CIRCUIT (HEAVY ARROWS ARE VECTORS OF TOTAL CURRENT)

meters from the short circuit the voltage vectors have rotated into coincidence, giving a maximum resultant equal to the sum of the lengths of the two vectors. Since the current reaches a minimum and the voltage a maximum value at this point, the impedance or ratio of voltage to current will be a maximum. Fig. 63 shows the total current and voltage at various distances from the short-circuited end, calculated by vectors as indicated in Fig. 62. The impedance and phase angle are also shown. The general form of the current distribution curve should be compared with the experimental curves shown in Figs. 7 to 9.

FIG. 62B—VOLTAGE AT VARIOUS DISTANCES FROM SHORT CIRCUIT (HEAVY ARROWS ARE VECTORS OF TOTAL VOLTAGE)

The three kilometers, or distance at which the impedance minimum was reached in Fig. 62, is a quarter of the length of a wave on the wire. Let us compare this result with that given by equation (38). Restating the equation.

$$E_x/I_x = Z \frac{I_1 e^{\gamma x} - I_2 e^{-\gamma x}}{I_1 e^{\gamma x} + I_2 e^{-\gamma x}} \quad (38)$$

In the case of a short-circuit reflection $I_2 = I_1$. Making this substitution in (38) and multiplying

numerator and denominator by $e^{-\gamma x}$, which simplifies the expression, we get

$$E_x/I_x = Z \frac{I_1 - I_1 e^{-2\gamma x}}{I_1 + I_1 e^{-2\gamma x}} = Z \frac{1 - e^{-2\gamma x}}{1 + e^{-2\gamma x}} \\ = Z \frac{1 - e^{-2\alpha x} e^{-j2\beta x}}{1 + e^{-2\alpha x} e^{-j2\beta x}} \quad (45)$$

which is the impedance of the line x kilometers from a short circuit reflection

In the case we have been considering $x = 3$ kilometers and the wire wave length $= n\lambda = 12$ kilo-

meters, so that $x = \frac{1}{4} n\lambda$. Since $\beta = \frac{2\pi}{n\lambda}$, βx

$$= \frac{2\pi}{n\lambda} \times \frac{n\lambda}{4} = \pi/2, \text{ and } 2\beta x = \pi. \text{ The factor}$$

FIG. 63—CURRENT, VOLTAGE, IMPEDANCE AND POWER FACTOR ANGLE ON SHORT-CIRCUITED LINE. (CURRENT AND VOLTAGE EXPRESSED AS RATIO TO THOSE OF WAVE REACHING REFLECTION POINT)

$e^{-j2\beta x}$ in (45) then becomes $e^{-j\pi} = \cos \pi - j \sin \pi = -1$ so that the impedance a quarter of a wire wave length from a short-circuit reflection is

$$Z_{max} = Z \frac{1 + e^{-2\alpha x}}{1 - e^{-2\alpha x}} \quad (46)$$

At six kilometers or a half wire wave length from the short-circuit reflection, we find in Fig. 62 that the total voltage is a minimum and the total current a maximum, so that the line impedance is at a minimum value.

Here $x = \frac{1}{2} n\lambda$, $\beta x = \frac{2\pi}{n\lambda} \times \frac{n\lambda}{2} = \pi$, and $2\beta x = 2\pi$. Therefore $e^{-j2\beta x} = e^{-j2\pi} = +1$. Using

this in (45) we find that the impedance a half wave length from a short-circuit reflection is

$$Z_{min} = Z \frac{1 - e^{-2\alpha x}}{1 + e^{-2\alpha x}} \quad (47)$$

The factor $e^{-j2\beta x}$ again reaches the value -1 , when $2\beta x$ becomes $3\pi, 5\pi, 7\pi, 9\pi, \dots$, or when the distance x is equal to any odd number of quarter wave lengths, and it becomes $+1$ when $2\beta x$ equals $2\pi, 4\pi, 6\pi, 8\pi, \dots$, or when x is an even number of quarter wave lengths. Therefore the impedance of a short-circuited line is expressed by (46) if x is an odd number of quarter wave lengths and by (47) if x is an even number of quarter wave lengths. (It being understood that "wave length" in this connection refers to the wire wave length, $n\lambda$)

In the case of an open-circuit reflection $I_2 = -I_1$, and the general expression (38) for impedance becomes

$$\begin{aligned} E_x/I_x &= Z \frac{I_1 e^{\gamma x} - I_2 e^{-\gamma x}}{I_1 e^{\gamma x} + I_2 e^{-\gamma x}} = Z \frac{I_1 e^{\gamma x} + I_1 e^{-\gamma x}}{I_1 e^{\gamma x} - I_1 e^{-\gamma x}} \\ &= Z \frac{1 + e^{-2\gamma x}}{1 - e^{-2\gamma x}} = Z \frac{1 + e^{-2\alpha x} e^{-j2\beta x}}{1 - e^{-2\alpha x} e^{-j2\beta x}} \quad (48) \end{aligned}$$

TABLE VIII
CONDITIONS FOR MAXIMUM OR MINIMUM IMPEDANCE OF LINE

Distance from point of reflection, wave lengths.....	1/4	2/4	3/4	4/4	5/4	6/4	7/4	8/4	9/4
Impedance, with short-circuit reflection.....	max.	min.	max.	min.	max.	min.	max.	min.	max.
Impedance, with open circuit reflection.....	min.	max.	min.	max.	min.	max.	min.	max.	min.

When $e^{-j2\beta x} = -1$, or when x is an odd number of quarter wave lengths, the impedance (48) takes the minimum value shown in (47), and when $e^{-j2\beta x} = +1$ or x is an even number of quarter wave lengths the impedance x kilometers from the end of the open-circuited line has the maximum value given by (46).

Summarizing, the impedance of the line takes the minimum value (47) or the maximum value (46), depending on the type of reflection and the distance from the reflection point, as shown in Table VIII. Since in the present case the impedance is to be measured at the end of the line we substitute l for x in (46) and (47) giving for the line input impedance.

$$Z_{max} = Z \frac{1 + e^{-2\alpha l}}{1 - e^{-2\alpha l}} \quad (46a)$$

$$Z_{min} = Z \frac{1 - e^{-2\alpha l}}{1 + e^{-2\alpha l}} \quad (47a)$$

In the foregoing discussion we have thought of the wave length as constant and the distance from the point of reflection as being varied, but a series of maxima and minima as indicated in Table VIII is also obtained if the length of the line is constant and the wave length, or frequency is changed. This is what is done when we take the measurements for plotting the input impedance curve like that shown in Fig. 60.

In Fig. 62 the minimum current or voltage is seen to be the difference between the lengths of the vectors of the forward and return waves. If these are very nearly equal, the impedance becomes very high at a

FIG. 64—CURVE FOR DETERMINING LINE ATTENUATION FROM IMPEDANCE RATIO

current node, and very low at a voltage node. On the other hand if the return wave is small compared with the forward wave, the impedance varies through a much smaller range. Thus the ratio of minimum to maximum impedance shows the magnitude of the return

wave as compared with the forward wave, or in other words it shows the attenuation which the waves undergo in traveling to the end of the line and back.

If the frequency of the current being supplied to the line, (in Fig. 61) is such that there are a whole number of quarter waves on the line, and we take measurements of the input impedance, with the far end open, and also with it short-circuited, we obtain a maximum impedance (46a) and a minimum impedance (47a) for the same frequency. Letting m stand for the ratio of the minimum to maximum impedance, we may calculate the attenuation as follows:

$$\begin{aligned} m &= Z_{min}/Z_{max} = \frac{Z \frac{1 - e^{-2\alpha l}}{1 + e^{-2\alpha l}}}{Z \frac{1 + e^{-2\alpha l}}{1 - e^{-2\alpha l}}} \\ &= \left(\frac{1 - e^{-2\alpha l}}{1 + e^{-2\alpha l}} \right)^2 \\ \sqrt{m} &= \frac{1 - e^{-2\alpha l}}{1 + e^{-2\alpha l}} \quad (49) \\ \sqrt{m} + 1 &= \frac{2}{1 + e^{-2\alpha l}} \end{aligned}$$

Fig. 69 shows the apparatus which the writers have used for measuring line input impedance. At either a voltage or current node the line is substantially a unity power factor load and its impedance may be determined by finding the non-inductive resistance which will give the same current. The pick-up coil should preferably have a low reactance compared with the impedance to be measured. When a current maximum is observed, the resistance is substituted for the line and the condenser C_2 adjusted to tune out the reactance of the pick-up coil. The circuit is then switched back to the line and the oscillator frequency readjusted to give current maximum. If the change of oscillator frequency has been considerable a repetition of the process will be needed. In the case of a low loss line it is desirable to use a relatively high-reactance pick up coil and high sensitivity meter for measuring the impedance maxima and a lower impedance coil

reflection. For a given frequency the line presents a definite impedance at its terminals, and adding resistance in the supply circuit merely reduces the current and voltage supplied to the line without altering the ratio of voltage to current at the line terminals.

It is desirable in some cases to check the values of line constants as determined from the input impedance, by direct measurement. Arrangement is made for telephone communication over the line as shown in Fig. 71 the circuits being designed to have negligible effect on the radio frequency currents. Various resistances are tried at the far end of the line, until a value is found which gives constant impedance at the oscillator end,

FIG. 70—CIRCUIT FOR MEASURING INPUT IMPEDANCE OF LOW LOSS LINES

over a considerable range of frequency. A small amount of reactance in addition to the resistance may be required to give perfectly constant impedance at the oscillator end, since the surge impedance is not necessarily a pure resistance. If the surge impedance changes with frequency a new resistance setting will be required for a different frequency range. Leaving the surge impedance as found in this way, in the far end of the line, simultaneous readings of the currents at the two ends are taken at a number of different frequencies, and the average ratio of received to supplied current gives the attenuation, $e^{-\alpha l}$. Measurements at different frequencies of the impedance of the line at the oscillator end give a check on the surge impedance as found by trial at the far end. The presence of partial reflections

FIG. 68—WAVE VELOCITIES OF ANTENNAS

FIG. 69—CIRCUIT FOR MEASURING ANTENNA INPUT IMPEDANCE FOR LONG WAVES

and less sensitive meter for measuring the low values of line impedance. Fig. 70 shows such an arrangement, indicating coil values which have been found suitable for a 10,000 to 20,000 meter range of wave lengths. Current transformers are permissible. Owing to the rapid change from low to high-current values precautions should be taken to avoid meter burn outs. Oscillator harmonics should be minimized by using large capacity C , and high-efficiency, low-inductance coils in the oscillator circuit, with loose coupling to the pick up coil.

It is not in all cases necessary to take the impedance characteristics of the line, both open and short-circuited. With a good set of readings for either condition, the envelope of the curves can be drawn in and the surge impedance and attenuation determined approximately.

It is not necessary to use a damping resistance at oscillator end of the line with a view to preventing

FIG. 71—CIRCUIT FOR DIRECT MEASUREMENT OF ATTENUATION

on the line, which may result from changes in ground conditions, may cause considerable error in the values of the constants as found by this method.

More complete and reliable information on the behavior of the line is obtained by supplying one end with current of constant frequency and amplitude, and measuring the current at intervals along the line, with different circuit conditions at the far end. If the end is damped with the true surge impedance, and there are no points of partial reflection on the line itself, the current will show a continuous decrease, following the exponential law. If the current is plotted as a function of distance on "semi log" paper, the points will fall on a straight line and the slope of the line will show the

attenuation constant. If reflections occur either at the end or at any other point on the line there will be humps or hollows in the curve. With the end open-circuited or grounded, this method of study shows the standing waves on the line, from which the velocity and attenuation can be calculated. Curves of this kind are shown in Figs. 3, 4, 5, 7, 8 and 9.

Interpretation of Observed Line Constants. The explanation of the manner in which velocity and attenuation are affected by frequency, is to be found in the varying depth of penetration of the return currents into the ground. Fig. 72 shows the general shape of the path of the ground current. There is a "skin effect" which tends to concentrate the earth currents near the surface. If it were not for this skin effect the mean depth of the earth currents in ground of uniform conductivity would be a considerable fraction of a wave length, probably between one and two thousand meters with a twelve thousand meter wave. As it is, most of the earth current is within one hundred meters of the surface, with waves of this length and soil of moderate conductivity. Zenneck's¹⁹ analysis gives the depths of penetration of earth currents for the case of space waves of plane wave front from which we can obtain a rough idea of the order of magnitude for the case of waves on a wire supported a short distance above earth.

FIG. 72—DISTRIBUTION OF GROUND CURRENTS UNDER WIRE CARRYING WAVES

If the earth carries current almost entirely by conduction rather than by capacity, which is true for all except short wave lengths or extremely high-resistance ground, Zenneck's formula for penetration may be stated in the following form.

$$D = 50 \sqrt{\rho/f}$$

in which D is the depth in meters at which the earth current density is reduced to $1/\epsilon = 0.368$ of its value at the surface.

ρ = specific resistance of the earth in ohms per centimeter cube.

f = frequency

This gives for a 12,000 meter wave ($f = 25,000$) and a specific resistance $\rho = 10^5$ ohms, a penetration $D = 100$ meters.

In Fig. 72 it is seen that there are both vertical and horizontal earth currents, but for the vertical currents the distance is relatively small and the cross section great. If the drawing were more nearly to scale this difference between the vertical and horizontal earth currents would be still more apparent. The conditions may be approximately represented by Fig. 73 in which a

small resistance is shown in series with the line to ground capacity and a higher resistance in the horizontal return conductor, which is at a depth corresponding to the mean depth of the earth currents. The capacity of such a line would be substantially the same as for a wire of the same height, over a perfectly conducting earth. The inductance would be that corresponding to a wire $H + D$ meters above a conducting plane which forms the return conductor. There would be a small added charging current loss due to the resistance in series with the capacity and a much larger loss due to the resistance of the horizontal return conductor. Since the depth of penetration increases with wave length we should expect greater inductance and therefore lower velocities on long waves. The greater the penetration the lower the resistance to the earth currents. Therefore the losses are less and the attenuation less on long waves. High-ground resistance increases the penetration and loss at the same time, and therefore reduces the velocity and increases the attenuation.

Beverage found for the sandy soil near Eastport, L. I. a specific resistance of about 2×10^6 ohms per centimeter cube. Since ground water occurs at a depth of something less than 100 feet (30 meters) the excess resistance and inductance of the Riverhead antenna are materially less than those corresponding to this value of soil resistance.

Table IX shows the calculated inductance and capacity of a one, two, and a four wire line based on perfectly conducting ground. The wire spacing is taken as 4 feet (1.3 meters) each way with 20 feet (6.6 meters) clear above ground.

TABLE IX.
CONSTANTS OF LINE OVER PERFECT GROUND

	1 wire	2 wires	4 wires
L_0 inductance, $\frac{m h}{k m}$, perfect ground.....	1.86	1.14	0.8
C_0 capacity, $\frac{m f}{k m}$, perfect ground.....	0.006	0.0098	0.0139
D-C. resistance of wires, $\frac{\text{ohms}}{km}$	3.3	1.64	0.82
R_w = A-C. ²⁰ resistance of wires			
at $f = 12,000 \sim$	4.44	2.22	1.11
20,000	5.50	2.75	1.38
30,000	6.6	3.3	1.64

The observed attenuation and velocity shown in Figs. 66 and 68, give a basis for calculating the effective inductance and resistance provided the capacity is known. The actual capacity is somewhat greater than C_0 as given above owing to insulators, poles, and the proximity of trees. An audio-frequency bridge measurement showed 0.011 microfarads per kilometer for two wires at a height of thirty feet. As this value seems

19. Translation given in Fleming "Principles of Electric Wave Telegraphy and Telephony" Third Edition P. 812.

20. Calculated by formula for skin effect given on page 135 of Principles of Electric Wave Telegraphy and Telephony, J. A. Fleming, 1916.

high and the accuracy of the bridge was not checked, we shall assume the capacity to be 10 per cent greater than the calculated value C_0 . This gives the constants shown in Table X for a two wire line.

TABLE X.

	Two Wire Line		
Frequency.....	12,000	20,000	30,000
u = observed velocity, km. per sec.....	2.33×10^8	2.37×10^8	2.42×10^8
$n = \frac{u}{3 \times 10^8}$ = velocity ratio.....	77.4	79	80.6
$L = \frac{1}{u^2 (1.1 C_0)}$ = effective inductance.....	1.73	1.66	1.59

$R_g = R - R_w$ = equivalent resistance of ground.....	24.3	31.75	39.7
ωL = Inductive reactance per kilometer...	131	208	300

The ground losses and penetration would not be materially different for the one and four wire lines. Taking the values of R_g and L_g for the two wire line as applicable to the one and four wire lines, we may calculate the attenuation and velocity to be expected on the latter as follows:

The formulas $Z = \sqrt{L/C}$, $\alpha = \frac{R}{2Z}$, and $u = \frac{1}{\sqrt{LC}}$

are approximations applicable when the resistance is small compared with the inductive reactance. In this

FIG. 73—CIRCUIT APPROXIMATELY EQUIVALENT TO GROUND

instance ωL is more than four times R for all the cases calculated and the errors in the magnitudes of α , u , and Z , due to the use of these abbreviated formulas are small. There is however an appreciable phase angle to the vector of the surge impedance Z , which it is of interest to estimate. If the losses were equally divided between dielectric and vertical ground current losses on the one hand and wire resistance and horizontal ground current losses on the other, or to put it differently if a short section of line with ground return had the same power factor, considered as an inductance as it has when treated as a condenser, then the surge impedance, would have zero phase angle or be equivalent to a pure resistance. In the present case the ground losses are for the most part equivalent to the effect of an added resistance in the line. If we assume all the losses to be the result of line resistance we shall obtain a maximum value for the phase angle of the surge

impedance. The full expression for surge impedance in vector terms is

$$Z = \sqrt{\frac{R + j\omega L}{G + j\omega C}}$$

in which G represents α shunt conductance of such value as to give the equivalent of all the dielectric loss.

The phase angle of Z is $1/2 \left(\tan^{-1} \frac{\omega L}{R} - \tan^{-1} \frac{\omega C}{G} \right)$

which becomes $-1/2 \tan^{-1} \frac{R}{\omega L}$ when $G = 0$. From

the values of L , C , and R given in the above tables we find the values for the surge impedance shown in Table XII. The figures preceded by $-j$ are ohms of capacity reactance. The actual amount of reactance would be slightly less than this, since G is not actually zero.

DIRECTIVE RECEPTION AND STRAY RATIO

Direction of Static. The general opinion that, on the average, summer static comes from a definite direction, for example from a southwesterly direction on our North Atlantic coast, seems to have been brought to a focus by Pickard's classical paper²¹ on "Static Elimination by Directional Reception." In the discussion Pickard cites an interesting note made by Marconi in 1906, giving the results of his observation on the directivity of static.

The remarks by Austin, Blatterman, Hoxie and Beverage are of particular interest in showing the trend of opinion as based on observation. The early work of Taylor²² is also of considerable interest in this connection. Taylor found that atmospherics were very strong on the high vertical antennas contemplated for European reception. After describing tests of various heights and lengths of antenna with the result that the signal to static ratio remained constant, he goes on to say—"One of the first questions that naturally arises in connection with these sturbs is, 'where do they come from?' and it was considered that if their office of origin could be located this might help solve the problem of their elimination. For this purpose an investigation has been conducted at the Belmar Station, where a directive antenna of the Bellini-Tosi type was erected." The conclusions from his observations are that static at Belmar has an average direction of south to southwest, as later observations have shown. Alexanderson²³ had also observed the marked directivity of static with his Barrage Receiver. More recently a great deal of very valuable systematic experimental work has been done by Austin²⁴ on this subject.

from certain directions. If static, while not confined to a specific direction, comes largely from a certain quarter, it is important to have an antenna system whose directive curve has a small area within the angle from which the heaviest static comes.

FIG. 74—DIRECTIVE CURVE OF LOOP

FIG. 75—DIRECTIVE CURVE OF COMBINED LOOP AND VERTICAL ANTENNA (EQUAL INTENSITIES)

A number of antenna arrangements have been used which are considerably more directive than the loop and vertical. The calculated directive curves of some of these are very similar to that of the one-wave-length, full-velocity wave antenna. Fig. 77 shows the directive curve of a pair of loops spaced apart in the direction of signal propagation, the currents from the two loops being combined in the receiving circuit in such phase as to neutralize for disturbances coming from a direction

opposite to the desired signal. The spacing of the loops is preferably between an eighth and a quarter wave length. Compared with systems which obtain their directivity in a small space, the full length wave antenna has the advantage mentioned in connection with the discussion of short wave antennas, namely, that the signal currents developed are strong in comparison with residuals, and therefore there is a better chance of

FIG. 76—DIRECTIVE CURVE FOR LOOP AND VERTICAL (VERTICAL GIVING HALF INTENSITY OF LOOP)

FIG. 77—DIRECTIVE CURVE FOR TWO LOOPS AN EIGHTH WAVE LENGTH APART

realizing in practise the directive properties predicted by calculation.

Reference to Figs. 35 to 41 and 44 shows that the areas of the directive curves of wave antennas are small, that the areas of the back and lobes of the curves are

very small so that disturbances coming from any direction more than 90 deg. from the signal have relatively small effect, and we have shown in the discussion of the reflection balance, that a blind spot can be produced for any direction more than 90 deg. from that of the signal. The benefit resulting from reduction in directive curve area is illustrated by the fact that in a number of comparisons the full wave antenna has always shown noticeably better stray ratios than an antenna half the length, although the difference in calculated area is comparatively slight.

Directive Effects for Impulses. The question will naturally arise whether directivity curves calculated for continuous waves, are applicable to the steep wave fronts and pulses of static. The experimental evidence is that they are applicable. It is clear that in the case of the wave antenna, waves on the wire will build up in the direction of travel of the space wave, and relatively feeble waves will reach the opposite end of the antenna, whatever the wave shape or number of waves in the train. As applied to antennas or circuits in which a balance of some sort is employed, to give zero reception for continuous waves from certain directions, the explanation of our experience with static is to be found in the great frequency selectivity of our receiving sets. Harmonic analysis of a pulse would show it to be equivalent to the sum of a large number of trains of waves of different frequencies. Of these the receiving set rejects all but the waves of signal frequency. Another view of the problem is the following:

Any circuit which produces a balance or zero reception for continuous waves of a certain frequency will react to a single pulse in such a way as to cause a second pulse in the opposite direction, simultaneously or a whole number of cycles later, or else a second pulse in the receiver in the same direction as the original, but an odd number of half cycles later. The receiving set has a tuned circuit and a detecting system which integrates over many cycles the effects of the oscillation of the tuned circuit. If the neutralizing pulse is simultaneous with the original, the tuned circuit is unaffected; otherwise the tuned circuit is set into oscillation by the initial pulse, but immediately stopped by the neutralizing pulse. The integrated effect of the brief oscillation is comparatively slight. If there were no neutralizing pulse the tuned circuit would (assuming a reasonably low loss circuit), execute something like a hundred oscillations before the amplitude is reduced to half the initial value.

While we have discussed static as if it consisted of single pulses or of waves of very high decrement, it may well be that some of our static consists of trains of many waves of a fairly constant frequency. The wave antenna, being aperiodic, provides a means of studying some of these disturbances without altering their character. If we insert an ordinary telephone receiver in the ground lead, at one end of a wave antenna, we hear a variety of "crackling" and "sputtering" noises,

some of which coincide with the static disturbances in the radio receiving sets. Among these noises is an occasional "ping," or sound of definitely musical character, resembling the sound given out when a bare telephone or telegraph wire is struck a sharp blow. No such sound in the receiver is heard, however, when the outside wire is actually struck.

The manner in which such continuous trains of waves might originate is not evident, but the following analogy is of interest. If you throw a stone into the water, you will note two or three circular waves as soon as the splash has subsided. Three or four seconds later you can count seven or eight waves, of substantially uniform size with a calm area inside, and after some ten seconds there may be a dozen to twenty waves. This analogy may have no significance in connection with ether waves, but it suggests a possibility. If it is true that static contains trains of waves of moderately low decrement, this would in part explain the failure of attempts to improve stray ratio by interior circuits (apart from the frequency selectivity obtainable by highly tuned circuits) and point to the conclusion that increased directivity must be our main reliance for further improvements in receiving through static.

GENERAL ENGINEERING FEATURES

Type of Construction. It is brought out in the discussion of the theory that, so far as collecting signal energy is concerned, there is no object in placing the wires of a wave antenna higher than is required for security and to pass obstructions. A high line will show slightly greater wave velocity and less attenuation than a low line, and be less affected by changes in ground conditions or proximity of trees, which sometimes cause sufficient changes in the line constants to give rise to slight reflections. The differences in favor of the higher line, however, are so small that they would rarely warrant the expense of taller poles.

Apart from the importance of a straight line and avoiding proximity of other conductors, the specifications for wave antenna construction might be taken bodily from those written for an open wire copper telephone circuit. Any change in construction or material which will appreciably alter the line impedance and give rise to reflections, should be avoided. Special care should be given to obtaining clean surfaces for making joints, since we are dealing with voltages which, on the average, are hardly a tenth of those developed in ordinary telephone circuits. Sleeve joints are recommended for permanence. The smallest copper wire which will stand the storms will make as satisfactory an antenna as a heavier wire. Good balance, where two wires are used, is important, and for this reason first-class insulation should be provided. We have seen that a single-wire antenna shows lower attenuation and higher velocity than a two wire antenna. For the same reasons, although in less degree, the use of small wire, and placing the wires near together (if

the antenna consists of several wires in multiple) is conducive to high velocity and small attenuation.

Except for temporary or experimental purposes, two-wire antennas are practically always desirable, since they permit adjustments in the station for putting out "back end" disturbances. The use of more wires will, in some cases, collect slightly more energy, but has no other advantage.

Whether a minimum of attenuation and a high velocity are desirable depends primarily on the length of the antenna. For an antenna a wave-length long, the best directive properties are obtained with a velocity between 0.7 and 0.8 of that of light. Higher velocities are desirable for longer antennas and lower velocities for shorter antennas. These considerations may govern the choice of number of wires, or other features of the design. It may even be desirable, in some cases, to reduce the wave velocity of the antenna below the natural value, by loading. The loading may be done by adding series inductance, with the effect of raising the line impedance and reducing the attenuation, as well as reducing the velocity. Slowing down the line by adding capacity to ground will lower the impedance and increase the attenuation. The amount of attenuation experienced on antennas consisting of bare wires on poles, does not appear to affect their directive properties adversely.

Location of Antenna. The land chosen for a wave antenna should be as flat and uniform as possible. The desired location of the receiving station need not control the selection of the location for the antenna. Parallels with other wire lines are to be avoided as far as possible, since the foreign lines, acting as antennas, pick up disturbance from various directions and introduce these into the antenna by induction. There is no simple way of balancing out this induction, for both the lines and the antenna are acting as ground return circuits. It is possible to prevent detrimental effects from adjacent

FIG. 78—EQUALLY CROOKED ANTENNAS WHICH ARE NOT EQUIVALENT

lines by loading them so as to prevent their carrying radio frequency currents. The importance of a straight right of way depends in part on the desired over-all velocity, which, in turn, depends on the length employed. Considerable deviations from a straight line affect the directive properties of the antenna, not only by reducing its wave velocity, but by altering the electromotive forces induced in it. For example, the antenna shown in Fig. 78A would receive disturbances from a direction at right angles to the mean line of the antenna, since the electromotive forces in the sections

$a-b$ and $d-c$ would by no means neutralize. On the other hand, in Fig. 78B, the sections $a-b$ and $c-b$, which are affected by disturbances at right angles to the antenna, are a small fraction of a wave length apart, and the effects of the disturbance would nearly neutralize each other in the two sections.

It is important to provide grounds at the ends of the antenna which will not change sufficiently to upset adjustments. A body of water in which several hundred feet of copper wire can be laid is the most desirable terminal for the antenna, but fairly satis-

FIG. 79—ARRANGEMENT PERMITTING LOCATION OF RECEIVING STATION AT A DISTANCE FROM THE ANTENNA

factory grounds can be made by burying sufficient lengths of wire. Beverage found on Long Island that, for grounds of this type, it was best to lay the wire in the sod rather than bury it deeper, since the humous of the surface soil retains its moisture better than the sand below. A star consisting of ten or a dozen 100 foot radii of 0.081 in. copper wire laid in this way usually gives a resistance as low as 20 to 40 ohms.

Location of Receiving Station. In the cases of the wave antennas which have so far been built, the receiving station has been located at the end nearest the transmitting station and the signals sent back over the transmission line as illustrated in Fig. 18. Figs. 79 and 80 show arrangements by which the receiving station may be located some distance from the antenna. Effective damping must be provided at the end A, and this can be done either by wasting most of the energy in a resistance at A and transmitting to the station only so much as is necessary for compensation, or by using close coupled transformers of proper ratio to fit the impedance of the circuits which they connect together, and effectively damping the transmission lines in the station. Experience has shown that signals can easily be transmitted a number of miles over open wire lines, with comparatively little loss of intensity, and if we start with signals of such intensity²⁵ as is usually obtained from a full wave length antenna, there is no perceptible impairment of stray ratio. For the transmission lines which are not a part of the antenna, there is no object in avoiding parallels with other

25. The quietness and balance of a two-wire transmission line are not absolute, and if we attempted to transmit very weak signals, they would obviously suffer in stray ratio.

circuits, but they should be transposed frequently enough to prevent picking up radio frequency currents by induction from other circuits.

Transmission lines will inevitably act as antennas and waves will be built up on them by disturbances traveling parallel with the direction of the transmission lines. If the lines are balanced, these waves will cause no difference of potential between wires, but only potentials to ground. Balanced transformers at the ends, with electrostatic shielding between primary and secondary, will in general suffice to prevent any effects of the parasitic waves from entering the receiver. Cases may arise, however, in which the waves built up on the transmission line are especially strong, making adequate balance difficult. There are several possible measures for reducing the antenna effects of the transmission lines, such as

1. Loading to give low velocity.
2. Sectionalizing with transformers.
3. Draining.

If the loading coils in the two wires are inductively coupled, they may be made to introduce comparatively

FIG. 80—ALTERNATIVE TO FIG. 79

little inductance in the transmission line and a higher inductance in the ground return line. A short-circuited secondary of suitable resistance will cause high loss to radio frequency currents in the two wires in multiple, but have no effect on the currents in the metallic circuit.

Sectionalizing as shown in Fig. 81 is one of the most effective means of preventing antenna effects in a transmission line. Drains from the neutrals of the transformer are also shown, to dissipate energy and prevent standing waves from building up.

Use of Existing Wires for Antenna. Existing copper wire lines, if uniform throughout the required length, and having the proper bearing, may be utilized as wave antennas. If the wires are in use for telegraph service, coils of 0.075 to 0.1 henry inductance may be used to isolate the part of the line which is to be used as an antenna. The remainder of the line may be drained through condensers if objectionable disturbances get past the coils into the antenna section. Unless the antenna ground is of very low resistance the ground for the drain should be separate, in order that disturbances shall not be carried through to the antenna, owing to

common resistance in the ground. Fig. 82 shows a circuit designed to isolate a portion of a telephone line for antenna purposes. This provides both chokes and a drain, and the coils and condensers are proportioned to cause minimum interference with the passage of the telephonic currents. If the grounding of the wires through the 0.3 microfarad condensers makes the telephone line noisy, a 0.2 microfarad condenser in the ground lead will reduce this tendency.

All parallel wires which are not used as part of the antenna should be sectionalized for radio frequency currents, either by coils, or by links of artificial line like that shown in Fig. 82, at intervals of a quarter or a third wave-length or less, of the shortest waves for which the antenna is to be used.

FIG. 81—SECTIONALIZING TRANSFORMER FOR TRANSMISSION LINES, WITH BY-PASS FOR DIRECT CURRENT

The principal disadvantages of using telegraph or telephone wires for an antenna are the compromise antenna design which is likely to result, and the difficulty of making tests on the antenna for balance or leakage. The latter applies especially to telegraph lines. If the wires are used for telephony only, large stopping condensers which will permit the telephone ringing currents to pass, may be introduced in series with the wires, at the ends of the antenna, thus permitting direct current tests to be made on the antenna.

Antenna Testing. In any permanent receiving system it should be possible, from the station, to test the continuity and insulation of the antenna and the balance or quietness of the transmission line. Fig. 83 shows an

FIG. 82—ISOLATION OF PART OF TELEPHONE LINE FOR USE AS ANTENNA

arrangement which Beverage applied to the Riverhead antenna. With the switch S_1 open, the line is insulated from ground and may be tested for leakage by voltmeter or megger. Throwing the switch S_2 to the battery side operates the relay at the far end of the antenna. This cuts out the reflection transformer, and if the transmission line is balanced the receiving set becomes almost entirely quiet. Fig. 84 shows the application of the same method of testing to the case where the receiving station is connected through transmission lines to the antenna. Arrangements for more complete tests are obviously possible, employing polarized relays or

selector switches, but the need of any more elaborate testing system has not yet arisen.

Protection. Potentials of several hundred volts are not uncommon on the wave antenna, even with no storm in the immediate vicinity. All coils which may have to stand these voltages should therefore have substantial insulation. Condensers rated at 1000 volts have been used in the installations at Belmar, Chatham, and Riverhead. Vacuum tube lightning arresters rated at 350 volts are connected between antenna wires and ground at both ends. The switch S_1 , in Fig. 83, is closed except during tests, to prevent static potentials from accumulating.

Apparatus Used with Wave Antenna. Some idea of the design of the essential pieces of apparatus which go with the wave antenna, may be of interest.

The reflection transformer for long wave work consists of three 84 turns "pancake" coils. The two outside coils in series constitute the secondary winding

FIG. 83—ARRANGEMENTS FOR INSULATING AND BALANCE TESTS

FIG. 84—RELAY CIRCUIT FOR TESTING ANTENNA OVER TRANSMISSION LINES

which is connected between the antenna wires. The middle coil, which is the primary winding, is connected from ground to the neutral of the secondary. Each coil is approximately 8 in. by 11 in. diameter by 1/2 in. thick. The conductor consists of seven strands of 0.010 in. wire with double cotton covering and a cotton braid, thus giving a loose, low-capacity winding. The whole transformer is placed in a wooden box which is filled with paraffin to exclude moisture. The following readings show the inductance:

Primary (84 turns) with secondary open.....	2.4 millihenrys	
Primary with secondary short-circuited.....	0.56	"
Secondary (168 turns) with primary open.....	7.5	"
Secondary with primary short-circuited.....	1.2	"

An arrangement suggested by Kellogg eliminates the

reflection transformer. This consists in grounding one wire of the antenna and leaving the other open-circuited. The signal wave currents built up on the antenna flow in the same direction in the two wires. When the waves reach the end of the antenna, reflections occur in opposite phase on the two wires, so that the waves which travel back toward the receiving station are of opposite sign, and are received by a transformer in the station connected across from wire to wire, exactly as is the case when a reflection transformer is used.

Iron core transformers have been used for the antenna output, or between the transmission line and the receiving set. The core is of 0.0015 in. enamelled iron, and is approximately a square inch in cross-section. The primary, or line winding, is in two equal coils of 60 turns each, placed symmetrically on the core and symmetrically with respect to the secondary windings. There are four secondary windings of 160 turns each with a grounded tinfoil shield between each winding and the next to prevent electrostatic coupling. The secondary windings are connected to the grids of pliotron tubes. A greater step-up ratio might have been employed, with consequent increase in signal strength, but the method of compensation, or "back end balance," did not provide sufficient potentials to permit using any more secondary turns on the output transformer.

Another type of antenna output transformer has been used in which the secondary winding is connected directly in series with a tuned circuit of the receiving set. This transformer was essentially like the one already described, except that the secondary windings were of ten turns each.

The artificial line which is used to adjust phase for the back end compensation, consists of a wooden cylinder 4 inches (10 cm.) in diameter, on which is wound a single layer 36 in. long of 0.0126 enamelled copper wire spaced 46 turns per inch. A tap is brought out, $\frac{3}{4}$ in. from the end, and every $1\frac{1}{2}$ inches thereafter, giving a total of 24 taps. A 0.005 microfarad condenser is connected from each winding tap to the common conductor, which forms the other side of the "line." A damping resistance of about 400 ohms, wound on a card, is connected across one end of the line. The line has an electrical length of about 16,000 meters and an intensity loss of about 5 per cent from end to end. Four sliders are provided, with double-contact phosphor bronze springs which bear lightly on the wires of the solenoid.

A trap to prevent interference from the transmitting station at Marion, Mass., which is directly in front of the Riverhead antenna, was used to advantage by Beverage. This consisted in a low-resistance series tuned circuit (about 15 millihenrys and a 0.005 microfarad variable air condenser) connected between the wires of the antenna in the station, thus shunting the primary of the output transformer. This formed such a low-impedance shunt when tuned to Marion's wavelength as to practically extinguish his signals. Subse-

quently, with receiving sets in which additional frequency selectivity was provided, this shunt trap was omitted, but it has a field of usefulness, and the high power factor of the circuit, where it is applied, makes its operation simple and satisfactory.

*Application to Short Waves.*²⁶ We have discussed the wave antenna as applied to long wave reception only; that is, to the reception of waves ranging from 7000 to 25,000 meters, used in transoceanic communication. It was in this field that the need of greater directivity in reception seemed most urgent, and in this field that the wave antenna was developed. The writers early demonstrated, in the short wave tests at Schenectady, that the wave antenna functioned in the same way on short waves as on long waves.

The first commercial application to shorter waves was the construction of a 2000-meter antenna at Chatham, Mass., for ship reception. This antenna was built in the summer of 1921 and is used for receiving traffic from ships having 1800 to 3000 meter continuous wave transmitting sets. It was in no wise a disappointment, for it resulted in a great improvement in reception, making it possible to receive ships from practically all the way across the Atlantic.

The next important trial of the wave antenna for short wave reception was during Mr. Paul F. Godley's transoceanic reception tests at Ardrossan, Scotland. Using a wave antenna about 400 meters long, pointed toward the United States, and using the best short wave receiving apparatus obtainable, Mr. Godley copied messages from many American amateur stations, on wave lengths between 200 and 300 meters. He attributed much of his success to his directive receiving antenna. Descriptions of the tests and of the antenna, written by Mr. Godley, were published in the February, 1922, Q. S. T., and the March, 1922, Wireless Age.

Recently the writers have done some experimenting with wave antennas for wave lengths in the 300 to 400 meter range. The advantage of the wave antenna on long waves in giving especially strong signals, is less apparent on short waves. The principal reason for this is that, for short waves, the static antennas or loops which we use as a basis of comparison are much larger in proportion to the wave antenna than is true in the case of antennas used in long wave reception.

The advantage, then, of the wave antenna for receiving waves of 450 meters or less, lies in its directive properties. Many amateurs wish to hear all the stations within range, but where the object is to receive from a certain direction only, and to exclude as much else as possible, the wave antenna will perform its function as well as on long waves.

The form of antenna best for short wave reception is practically the same as for long waves, although it will in general be desirable to reduce the height, in

order to lessen the effect of the vertical conductors at the ends. Fig. 85 shows suitable arrangements for short wave reception. The surge impedance for a given type of construction will be slightly less on short waves than on long waves. The double wire antenna with reflection transformer has a decided advantage in convenience compared with a single-wire antenna. The equivalent of the reflection transformer—namely, grounding one wire and leaving the other open-circuited, will, as a rule, be preferred for its simplicity. Rear end compensation by means of the reflection balance is desirable and easily applied. This calls for a series-tuned circuit in series with the surge impedance, as shown in Fig. 85. The resistance should be variable and the capacity reactance and inductive reactance should preferably not exceed about 500 ohms each. For output a coil of about 0.1 millihenry in the ground lead of a single-wire antenna, or, if the reflection transformer system is followed, a 0.2 millihenry coil connected between the two wires of the antenna is suitable. The first tuned circuit of the receiving set may then be coupled to this output coil.

FIG. 85—ARRANGEMENTS FOR SHORT WAVE RECEPTION

APPENDIX A

Typical Operations with Vector Quantities

For additions or subtractions, vectors must be expressed in terms of their components,

$$(a + j b) + (c + j d) = (a + c) + j (b + d)$$

$$(a + j b) - (c + j d) = (a - c) + j (b - d)$$

The vector $a + j b$ has a length $\sqrt{a^2 + b^2}$ and an angle $\tan^{-1} b/a$.

Letting φ stand for the angle $\tan^{-1} b/a$, $a = \sqrt{a^2 + b^2} \cos \varphi$ and $b = \sqrt{a^2 + b^2} \sin \varphi$ whence $a + j b = \sqrt{a^2 + b^2} (\cos \varphi + j \sin \varphi)$.

There are several other ways of expressing a vector in terms of its length and angle $a + j b = (\sqrt{a^2 + b^2}) e^{j\varphi}$ if φ is expressed in radians or $a + j b = (\sqrt{a^2 + b^2}) e^{j(\varphi^\circ/57.3)}$ if φ° is expressed in degrees. $a + j b = \sqrt{a^2 + b^2} / \varphi$ if we define the symbol $/\varphi$ as meaning that the quantity $\sqrt{a^2 + b^2}$ after which it appears is to be multiplied by $\cos \varphi + j \sin \varphi$.

The identity of $e^{j\varphi}$ and $\cos \varphi + j \sin \varphi$ is most readily shown by expanding $e^{j\varphi}$, $\cos \varphi$, and $\sin \varphi$ in power series, and replacing j^2 by -1 . This relation is shown in a number of text books.

The product of two vectors is found by multiplying their lengths together and adding their angles.

26. For more detailed discussion of the application to short wave reception, see article by H. H. Beverage in Q. S. T., Nov. 1922.

$$\text{Thus } (A/\varphi_1)(B/\varphi_2) = A \times B / \varphi_1 + \varphi_2$$

$$(a + jb)(c + jd) = (\sqrt{a^2 + b^2})(c^2 + d^2) / \tan^{-1} b/a + \tan^{-1} d/c$$

To divide one vector quantity by another we take the quotient of their lengths and the difference of their

$$\text{angles, } \frac{A/\varphi_1}{B/\varphi_2} = A/B / \varphi_1 - \varphi_2.$$

Multiplication and division may also be performed with the vectors in the form $a + jb$, thus $(a + jb)(c + jd) = ac + jad + jbc + j^2 bd = (ac - bd) + j(ad + bc)$

$$\frac{a + jb}{c + jd} = \frac{(a + jb)}{(c + jd)} \times \frac{(c - jd)}{(c - jd)}$$

$$= \frac{(ac + bd) + j(-ad + bc)}{c^2 + d^2}$$

In the foregoing any component or any angle may have a negative sign.

In the expression $a + jb = \sqrt{a^2 + b^2}(\cos \varphi + j \sin \varphi)$ where $\varphi = \tan^{-1} b/a$ the quantity $\sqrt{a^2 + b^2}$ taken by itself would have zero phase angle, and the quantity $(\cos \varphi + j \sin \varphi)$ has a phase angle φ and a length unity (since $\cos^2 \varphi + \sin^2 \varphi = 1$ and therefore $\sqrt{\cos^2 \varphi + \sin^2 \varphi} = 1$). Multiplying by $\cos \varphi + j \sin \varphi$, or its equivalent $e^{j\varphi}$ thus simply causes a counter-clockwise rotation or phase advance by the amount of the angle φ . Multiplying by $e^{-j\varphi}$ or $\cos(-\varphi) + j \sin(-\varphi)$ which is $\cos \varphi - j \sin \varphi$, causes clockwise rotation or phase retardation by the amount of the angle φ .

From the rule for multiplication it follows that to square a vector quantity we square its length and double its angle. Thus $(A/\varphi)^2 = A^2/2\varphi$ and conversely to find the square root of a vector we take the square root of its length and divide its angle by two, $\sqrt{A/\varphi} = \sqrt{A}/1/2\varphi$.

Differentiation of a vector quantity A , with respect to some variable X , on which A depends, gives the vector change in A per unit change in X .

$$\frac{dA}{dX} = \frac{A_2 - A_1}{x_2 - x_1}$$

in which $A_2 - A_1$ is a vector difference, A_1 is the value of A corresponding to X_1 and A_2 that corresponding to X_2 , and X_2 differs from X_1 by an infinitesimal amount.

In Fig. 62A a vector connecting the ends 1 and 2 of the total current vectors, corresponding to $x = 1$

and $x = 2$, would represent $\frac{dI}{dX}$ corresponding to a value 1.5 for X .

Integration of a vector quantity gives the vector sum of an infinite number of infinitesimal vectors. This process is illustrated, using finite numbers, in Figs. 28 and 33.

APPENDIX B

Analysis of Action of Wave Antenna

The following treatment of the problem of the wave antenna, was worked out by Mr. Ivar Herlitz or Kellogg's request. Mr. Herlitz was at the time pursuing graduate studies in electrical engineering at Union College as exchange student of the American Scandinavian Foundation. The treatment is given here partly by way of acknowledgment for the substantial assistance derived from Mr. Herlitz's solution of the problem, at an early date in the evolution of the theory of the antenna, and partly because the equations are derived in a radically different manner, and provide a valuable means of checking results as calculated by the expressions given in the body of the paper.

Referring to Fig. 26, x is a distance measured along the antenna from the end A , nearest the source of signals, and l is the total length of the antenna.

As in the discussion given in the paper, the induced voltage per unit length of wire at the point X , is taken as

$$E_x = E_0 \cos \theta e^{-j\omega x (\cos \theta)/v}$$

The following new symbols will be used.

i = current in wire at X

e = potential of wire at X , with respect to ground.

The potential gradient along wire is the resultant of that due to the passage of current through the line inductance and resistance, and the voltage induced in the wire by the space wave, or

$$\frac{de}{dx} = -(R + j\omega L)i + E_0 \cos \theta e^{-j\omega x (\cos \theta)/v} \quad (52)$$

The current in the wire changes from point to point by the amount of the leakage and charging currents, or

$$\frac{di}{dx} = -(G + j\omega C)e \quad (53)$$

Differentiating (53) and solving for $\frac{de}{dx}$ gives

$$\frac{d^2 i}{dx^2} = -(G + j\omega C) \frac{de}{dx}$$

$$\frac{de}{dx} = -\frac{1}{(G + j\omega C)} \frac{d^2 i}{dx^2} \quad (54)$$

Substituting this in (52) and multiplying through by $-(G + j\omega C)$ gives

$$\frac{d^2 i}{dx^2} = (R + j\omega L)(G + j\omega C)i$$

$$- (G + j\omega C)E_0 \cos \theta e^{-j\omega x (\cos \theta)/v} \quad (55)$$

or since $(R + j\omega L)(G + j\omega C) = \gamma^2$

$$\frac{d^2 i}{dx^2} = \gamma^2 i - (G + j\omega C)E_0 \cos \theta e^{-j\omega x (\cos \theta)/v} \quad (56)$$

Use trial solution of the form

$$i = A e^{\gamma x} + B e^{-\gamma x} + D e^{-j\omega x (\cos \theta)/v} \quad (57)$$

Differentiating (57)

$$\frac{d i}{d x} = \gamma A e^{\gamma x} - \gamma B e^{-\gamma x} - j \frac{\omega \cos \theta}{v} D e^{-j \omega x (\cos \theta)/v} \quad (58)$$

$$\frac{d_2 i}{d x_2} = \gamma^2 A e^{\gamma x} + \gamma^2 B e^{-\gamma x} - \frac{\omega^2 \cos^2 \theta}{v^2} D e^{-j \omega x (\cos \theta)/v} \quad (59)$$

We next substitute the value of i given in (57) and the value of $\frac{d_2 i}{d x_2}$ given in (59) in equation (56)

$$\begin{aligned} \gamma^2 A e^{\gamma x} + \gamma^2 B e^{-\gamma x} - \frac{\omega^2 \cos^2 \theta}{v^2} D e^{-j \omega x (\cos \theta)/v} \\ = \gamma^2 A e^{\gamma x} + \gamma^2 B e^{-\gamma x} + \gamma^2 D e^{-j \omega x (\cos \theta)/v} \\ - (G + j \omega C) E_0 \cos \theta e^{-j \omega x (\cos \theta)/v} \end{aligned}$$

from which

$$\begin{aligned} D \left(\gamma^2 + \frac{\omega^2 \cos^2 \theta}{v^2} \right) &= (G + j \omega C) E_0 \cos \theta \\ D &= \frac{(G + j \omega C) E_0 \cos \theta}{\gamma^2 + \frac{\omega^2 \cos^2 \theta}{v^2}} \quad (60) \end{aligned}$$

Using this value of D in (57), we have as the general expression for current

$$\begin{aligned} i &= A e^{\gamma x} + B e^{-\gamma x} \\ &+ \frac{(G + j \omega C) E_0 \cos \theta}{\gamma^2 + \frac{\omega^2 \cos^2 \theta}{v^2}} e^{-j \omega x (\cos \theta)/v} \quad (61) \end{aligned}$$

The constants A and B depend on the terminal impedance and we must find an expression for the voltage e , as well as the current i , in order to evaluate them.

From (53)

$$e = - \frac{1}{(G + j \omega C)} \frac{d i}{d x}$$

in which we may substitute the value of $\frac{d i}{d x}$ given in

(58) using the value given in (60) for D

$$\begin{aligned} e &= \frac{-\gamma A e^{\gamma x}}{G + j \omega C} + \frac{\gamma B e^{-\gamma x}}{G + j \omega C} \\ &+ \frac{j \frac{\omega \cos \theta}{v} E_0 \cos \theta}{\gamma^2 + \frac{\omega^2 \cos^2 \theta}{v^2}} e^{-j \omega x (\cos \theta)/v} \end{aligned}$$

Since $\frac{\gamma}{G + j \omega C} = Z$, the expression for e becomes,

$$\begin{aligned} e &= -Z A e^{\gamma x} + Z B e^{-\gamma x} \\ &+ \frac{j \frac{\omega \cos \theta}{v} E_0 \cos \theta}{\gamma^2 + \frac{\omega^2 \cos^2 \theta}{v^2}} e^{-j \omega x (\cos \theta)/v} \quad (62) \end{aligned}$$

For an antenna with non-reflecting ends, or in other words, with the surge impedance at each end,

$$e = -Z i \text{ for } x = 0$$

$$e = +Z i \text{ for } x = l$$

Using the expressions for i and e given in (61) and (62) we set $x = 0$ and equate $-Z i$ to e , and have

$$\begin{aligned} -Z A - Z B - Z \frac{(G + j \omega C) E_0 \cos \theta}{\gamma^2 + \frac{\omega^2 \cos^2 \theta}{v^2}} \\ = -Z A + Z B + \frac{j \frac{\omega \cos \theta}{v} E_0 \cos \theta}{\gamma^2 + \frac{\omega^2 \cos^2 \theta}{v^2}} \end{aligned}$$

whence

$$\begin{aligned} -2Z B &= \frac{E_0 \cos \theta}{\gamma^2 + \frac{\omega^2 \cos^2 \theta}{v^2}} \left\{ j \frac{\omega \cos \theta}{v} \right. \\ &\quad \left. + Z (G + j \omega C) \right\} \end{aligned}$$

and since $Z (G + j \omega C) = \gamma$

$$\begin{aligned} B &= - \frac{E_0 \cos \theta}{2Z} \frac{\gamma + j \frac{\omega \cos \theta}{v}}{\gamma^2 + \frac{\omega^2 \cos^2 \theta}{v^2}} \\ &= - \frac{E_0 \cos \theta}{2Z \left[\gamma - j \frac{\omega \cos \theta}{v} \right]} \quad (63) \end{aligned}$$

Next setting $x = l$ in (61) and (62) and equating $+Z i$ to e we have

$$\begin{aligned} Z A e^{\gamma l} + Z B e^{-\gamma l} \\ + Z \frac{(G + j \omega C) E_0 \cos \theta}{\gamma^2 + \frac{\omega^2 \cos^2 \theta}{v^2}} e^{-j \omega l (\cos \theta)/v} \\ = -Z A e^{\gamma l} + Z B e^{-\gamma l} \\ + \frac{j \frac{\omega \cos \theta}{v} E_0 \cos \theta}{\gamma^2 + \frac{\omega^2 \cos^2 \theta}{v^2}} e^{-j \omega l (\cos \theta)/v} \\ 2Z A e^{\gamma l} = \\ \frac{E_0 \cos \theta e^{-j \omega l (\cos \theta)/v}}{\gamma^2 + \frac{\omega^2 \cos^2 \theta}{v^2}} \left[j \frac{\omega \cos \theta}{v} - Z (G + j \omega C) \right] \\ = - \frac{E_0 \cos \theta e^{-j \omega l (\cos \theta)/v}}{\gamma^2 + \frac{\omega^2 \cos^2 \theta}{v^2}} \left[\gamma - j \frac{\omega \cos \theta}{v} \right] \\ = - \frac{E_0 \cos \theta e^{-j \omega l (\cos \theta)/v}}{\gamma + j \frac{\omega \cos \theta}{v}} \end{aligned}$$

$$\begin{aligned} A &= \frac{-E_0 \cos \theta e^{-j \omega l (\cos \theta)/v}}{2Z e^{\gamma l} \left(\gamma + j \frac{\omega \cos \theta}{v} \right)} \\ &= - \frac{E_0 \cos \theta e^{-(\gamma + j \frac{\omega \cos \theta}{v}) l}}{2Z \left(\gamma + j \frac{\omega \cos \theta}{v} \right)} \quad (64) \end{aligned}$$

With these values for A and B and with γ/Z substituted for $G + j\omega C$, equation (61) for current becomes

$$i = E_0 \cos \theta \left\{ \frac{-\epsilon^{-(\gamma + j\omega l (\cos \theta)/v)}}{2Z \left(\gamma + j \frac{\omega \cos \theta}{v} \right)} e^{\gamma x} - \frac{1}{2Z \left(\gamma - j \frac{\omega \cos \theta}{v} \right)} e^{-\gamma x} + \frac{\gamma \epsilon^{-j\omega l (\cos \theta)/v}}{Z \left(\gamma^2 + \frac{\omega^2 \cos^2 \theta}{v^2} \right)} \right\} \quad (65)$$

The receiver end current is found by letting $x = l$ in (65) which gives

$$\begin{aligned} i_b &= E_0 \cos \theta \left\{ \frac{-\epsilon^{-(\gamma + j\omega l (\cos \theta)/v)}}{2Z \left(\gamma + j \frac{\omega \cos \theta}{v} \right)} e^{\gamma l} - \frac{\epsilon^{-\gamma l}}{2Z \left(\gamma - j \frac{\omega \cos \theta}{v} \right)} + \frac{\gamma \epsilon^{-j\omega l (\cos \theta)/v}}{Z \left(\gamma^2 + \frac{\omega^2 \cos^2 \theta}{v^2} \right)} \right\} \\ &= \frac{E_0 \cos \theta}{2Z} \left\{ \frac{-\epsilon^{-j\omega l (\cos \theta)/v}}{\gamma + j \frac{\omega \cos \theta}{v}} - \frac{\epsilon^{-\gamma l}}{\gamma - j \frac{\omega \cos \theta}{v}} + \frac{2\gamma \epsilon^{-j\omega l (\cos \theta)/v}}{\left(\gamma + j \frac{\omega \cos \theta}{v} \right) \left(\gamma - j \frac{\omega \cos \theta}{v} \right)} \right\} \\ &= \frac{E_0 \cos \theta}{2Z} \frac{\epsilon^{-j\omega l (\cos \theta)/v}}{\left(\gamma - j \frac{\omega \cos \theta}{v} \right)} \times \left\{ - \frac{\left(\gamma - j \frac{\omega \cos \theta}{v} \right)}{\gamma + j \frac{\omega \cos \theta}{v}} - \epsilon^{-\gamma l} \epsilon^{+j\omega l (\cos \theta)/v} + \frac{2\gamma}{\gamma + j \frac{\omega \cos \theta}{v}} \right\} \\ &= \frac{E_0 \cos \theta \epsilon^{-j\omega l (\cos \theta)/v}}{2Z \left(\gamma - j \frac{\omega \cos \theta}{v} \right)} \times \left\{ \frac{\gamma + j \frac{\omega \cos \theta}{v}}{\gamma + j \frac{\omega \cos \theta}{v}} - \epsilon^{-(\gamma - j\omega l (\cos \theta)/v)} \right\} \\ &= \frac{E_0 \cos \theta \epsilon^{-j\omega l (\cos \theta)/v}}{2Z \left(\gamma - j \frac{\omega \cos \theta}{v} \right)} \{1 - \epsilon^{-(\gamma - j\omega l (\cos \theta)/v)}\} \end{aligned}$$

$$= \frac{E_0 \cos \theta \epsilon^{-j\omega l (\cos \theta)/v}}{2Z [\alpha + j\beta (1 - n \cos \theta)]} \times \{1 - \epsilon^{-[\alpha + j\beta (1 + n \cos \theta)] l}\} \quad (66)$$

The back end current is found by setting $x = 0$ in (65) which gives

$$\begin{aligned} i_a &= E_0 \cos \theta \left\{ \frac{-\epsilon^{-(\gamma + j\omega l (\cos \theta)/v)}}{2Z \left(\gamma + j \frac{\omega \cos \theta}{v} \right)} - \frac{1}{2Z \left(\gamma - j \frac{\omega \cos \theta}{v} \right)} + \frac{\gamma}{Z \left(\gamma + j \frac{\omega \cos \theta}{v} \right) \left(\gamma - j \frac{\omega \cos \theta}{v} \right)} \right\} \\ &= \frac{E_0 \cos \theta}{2Z \left(\gamma + j \frac{\omega \cos \theta}{v} \right)} \left\{ -\epsilon^{-[\gamma + j\omega l (\cos \theta)/v] l} - \frac{\gamma + j \frac{\omega \cos \theta}{v}}{\gamma - j \frac{\omega \cos \theta}{v}} + \frac{2\gamma}{\gamma - j \frac{\omega \cos \theta}{v}} \right\} \\ &= \frac{E_0 \cos \theta}{2Z \left(\gamma + j \frac{\omega \cos \theta}{v} \right)} \{1 - \epsilon^{-[\gamma + j\omega l (\cos \theta)/v] l}\} \\ &= \frac{E_0 \cos \theta}{2Z [\alpha + j\beta (1 + n \cos \theta)]} \times \{1 - \epsilon^{-[\alpha + j\beta (1 + n \cos \theta)] l}\} \quad (67) \end{aligned}$$

APPENDIX C

List of Symbols

Symbols in heavy faced type, as I, E, Z stand for vector quantities.

L = Series inductance of antenna conductors, henrys per kilometer.

C = Shunt capacity of antenna, farads per kilometer

R = Effective series resistance of antenna, ohms per kilometer

G = Leakage conductance to ground, mhos for one kilometer, (effective value at high frequency)

Z = Characteristic or surge impedance of antenna

$$Z = \sqrt{\frac{R + j\omega L}{G + j\omega C}} \text{ or for most purposes at radio frequency } Z = \sqrt{L/C}$$

γ = Propagation constant for antenna

$$\gamma = \sqrt{(R + j\omega L)(G + j\omega C)}$$

α = Attenuation constant per kilometer = real part of γ . If ωL is large compared with R , and ωC large compared with G , $\alpha = R/2 \sqrt{C/L} + G/2 \sqrt{L/C}$ approximately

$j\beta$ = Imaginary component of γ , or β = Wave length constant of Antenna. $\gamma = \alpha + j\beta$. For most purposes at radio frequency $\beta = \omega \sqrt{LC}$ approximately

- u = Antenna wave velocity, kilometers per second
 $u = \omega/\beta$ or $u = 1/\sqrt{LC}$ approximately
- v = Velocity of space waves
 = Velocity of light = 3×10^5 kilometers per second
- n = Velocity ratio of antenna = u/v
- f = frequency of signal waves, cycles per second
- λ = Signal wave length = $\frac{3 \times 10^5}{f}$ kilometers
- $\omega = 2\pi f$
- e = Base of natural logarithms = 2.718 $e^x = 10^{0.4343 x}$
- l = Length of antenna in kilometers
- θ = Angle between direction of signal and direction of antenna
- E_0 = Measure of signal intensity = Induced volts per kilometer in horizontal conductor parallel to signal direction
- I_b = Current at receiver end of antenna (both ends of antenna assumed to be damped by surge impedance)
- I_a = Current at back end of antenna (both ends assumed damped)
- ρ = Specific resistance of earth, ohms for one centimeter cube.

Discussion

H. H. Beverage: Since the wave antenna paper was written, more quantitative measurements have been made on the effective height of the wave antenna. The measurements mentioned

in the paper gave the ratio of horizontal to vertical voltage gradient as 30 per cent. This measurement was based on comparatively few observations and was not checked simultaneously against an antenna of known effective height. Furthermore, the measurements were based on vertical gradients calculated by Austin's formula, which gives values much lower than observed values at certain periods of the day.

Recently, a much more accurate quantitative method has been developed for measuring signal intensity, and many measurements have been made on the wave antenna at Belmar. In this case, the effective height of the wave antenna was determined by simultaneous observations on a vertical antenna of known effective height. Measurements made by H. H. Beverage and H. O. Peterson indicated that the average effective height of the Belmar long wave antenna was 200 meters. Since the horizontal length was 12,500 meters, the horizontal potential gradient is 1.6 per cent of the vertical potential gradient. At 11,000 meters, the effective height was somewhat greater than this average value, and at 19,000 meters the effective height was lower than the average value. These observations give the same order of magnitude as the calculations by Zenneck's formula for wave tilt.

On short wave lengths, that is, 200 to 600 meters, the horizontal gradient appears to be around 5 per cent to 6 per cent of the vertical gradient over soil of moderately low conductivity such as is found at Belmar. This increase in tilt with shorter wave length is in accordance with Zenneck's formula.

A further check on the wave tilt theory has been noted by comparing the effective height of short wave antennas over earth of high and low conductivity. These antennas were about 400 meters long, and measurements made by Peterson on 400 meters indicated that the signal strength on an antenna over moderately conducting ground was three to four times as great as on a similar antenna partly over salt water and partly over a marsh. In this case, comparisons were made directly with a local loop in order to check the field intensity in the vicinity of the wave antennas.

Dissymmetrical Electrical Conducting Networks

BY A. E. KENNELLY

Fellow, A. I. E. E.,
Professor of Electrical Engineering, Harvard University and Mass. Inst. Technology

IT is well known that a symmetrical T -connection of three simple impedances $a o$, $o b$, and $o q$, Fig. 1, in which the two arms $a o$, and $b o$ are electrically equal, and with their common terminal o connected to the ground or return conductor $g h$ through the impedance $o q$, can be completely replaced,* at any single assigned alternating-current frequency, by a certain symmetrical π , $a' b' g' h'$, Fig. 2, in which the two pillars $a' g'$ and $b' h'$, have equal impedances; also that either of these two symmetrical systems can be completely replaced, at the same frequency,† by a single smooth line conductor $a'' b''$, Fig. 3, having uniformly distributed series impedance in its conductor and also uniformly distributed lateral leak admittance between the conductor and the return conductor $g'' h''$. Such a line conductor may be regarded as subtending or

conducting system of Fig. 1, and the symmetrical π of Fig. 2, may be regarded as possessing the same complex angle θ and surge impedance z_0 , by virtue of equivalence. In any network of conductors, carrying alternating currents of the assigned frequency in the steady state, any of the three equivalent systems of Figs. 1,

FIG. 1, 2 AND 3—SYMMETRICAL T , π AND SMOOTH LINE, EQUIVALENT AND INTERCHANGEABLE

possessing, at the frequency in question, a certain complex hyperbolic angle θ , and also a certain single surge impedance or "characteristic impedance," z_0 ohms. Consequently, both the symmetrical T con-

FIGS. 4, 5 AND 6—COMPOSITE LINE OF THREE SECTIONS WITH ITS EQUIVALENT DISSYMMETRICAL T AND π

2 and 3 may be interchanged, without disturbing the distributions of potential, current and power, at and outside the terminals of the system.

Moreover, if two or more simple smooth line conductors, of the type indicated in Fig. 3, are connected in series to form a composite line as in Fig. 4, it is known that the composite line system $a'' b'' g'' h''$ (Fig. 4) can be replaced by its equivalent T of Fig. 5,‡ or by its equivalent π of Fig. 6, and that these equivalent conductors are, in general, dissymmetrical. For a given composite-line system of Fig. 4 operated in the steady state at a single frequency, there can be only one equivalent T and also only one equivalent π . On the other hand, neither the equivalent T of Fig. 5, nor the equivalent

* Bibliography (1).

† Bibliography (3).

‡ Bibliography (4).

lent π of Fig. 6 can determine the elements of smooth line section in the equivalent composite-line system of Fig. 4. In the absence of specific information concerning the number and characters of the component-line sections, an infinite number of different composite-line systems like that of Fig. 4, could be found as equivalents for the dissymmetrical T or π of Figs. 5 and 6. The question thus arises as to what is the simplest smooth-line system which can replace a given

FIG. 7—NETWORK OF IMPEDANCES REPLACEABLE BY ONE DISSYMMETRICAL T OR π WITH RESPECT TO THE TWO PAIRS OF TERMINALS, a, g , AND b, h .

dissymmetrical T and its corresponding dissymmetrical π ?

Again, if any network of conductors, such as that of Fig. 7, carrying alternating currents of a single frequency, and two pairs of terminals are selected arbitrarily from the system, such as a, g , and b, h ; then the system behaves with respect to these pairs of terminals like a certain equivalent T of Fig. 5, and also like the corresponding equivalent π of Fig. 6, these two systems being mutually equivalent and, in general, dissymmetrical. The question then also arises as to what is the simplest smooth-line conductor system which can be regarded as replacing the network, with respect to the pairs of terminals a, g and b, h ?

A symmetrical network of conductors, with respect to two pairs of terminals, may be defined as one whose equivalent T and π are symmetrical, like Figs. 1 and 2. A dissymmetrical network is then one which, with respect to the two pairs of terminals, has a dissymmetrical equivalent T and π , like Figs. 5 and 6. In general, networks are dissymmetrical, and symmetrical networks are particular cases.

Although we always discuss a network with reference to two pairs of terminals, such as a, g and b, h in Fig. 7; yet the number of terminals involved may be reduced, in particular cases, from four to three, by the merging of two terminals. Thus, we might select the two pairs of terminals, a, g and b, g , which employ the terminal g in common.

As has already been pointed out, a network which is symmetrical with respect to two pairs of terminals becomes defined either by a certain symmetrical T and π , or by a certain hyperbolic angle θ and accompanying surge impedance z_0 . We can then readily compute what changes in alternating-current potential

difference, current and power will be brought about at one of the pairs of terminals by any assigned electric change steadily impressed on the other pair. When, however, the network is dissymmetrical, we shall find that it requires for its definition one additional characteristic. A convenient additional characteristic is the "inequality ratio" q ; so that the network acquires three characteristics θ , z_{ab} and q , which are capable of being measured in any given case, by following a suitable technique at each pair of terminals. Having ascertained these three determining characteristics for the network, we can either draw immediately its equivalent T and π ; or we can compute what change in potential difference, current and power will be produced at one pair of terminals, say a, g , by a given change established steadily at the other pair b, h .

FIGS. 8, 9 AND 10—DISSYMMETRICAL T REDUCED TO SYMMETRY BY THE RETENTION OF A PERMANENT SERIES LOAD AT THE b TERMINAL WITH THE CORRESPONDINGLY LOADED π AND SMOOTH LINE.

The computation is effected by following the same process as in the symmetrical case; but with a slight modification.

The subject can best be studied with reference to continuous-current lines and networks; *i. e.*, with reference to the frequency of zero. The results so obtained are immediately applicable to alternating-

current systems, by the substitution of complex numbers for real numbers, in the well known way.

Fig. 8 shows a simple dissymmetrical T . In this particular case the branch $a o$ has 1000 ohms and the branch $b o$ 2000 ohms. Two methods suggest themselves for dealing with it; namely, (1) by reducing it to a terminally loaded symmetrical T , and (2) by retaining the dissymmetry, but making measurements from each end in turn. We may consider these two methods successively.

(1) *Method of Reduction to Symmetry.* The simplest way to reduce the T a, o, b of Fig. 8 to symmetry, is perhaps to cut off the portion B, b from the preponderating arm, so as to leave the remainder o, B equal to the branch a, o . We thus obtain symmetrical T a, o, B with a load B, b , in this case 1000 ohms, permanently attached to the terminal B . The corresponding loaded symmetrical π is shown in Fig. 9; where the same load B', b' , is permanently attached to the B' terminal. Fig. 10 gives the terminally loaded smooth line $a'' B''$, corresponding to the combinations of Figs. 8 and 9. It has an angle of 0.622362 hyp., a surge resistance of $z_0 = 3316.63$ ohms, a total conductor resistance R of 2064.14 ohms and a total leakance G of 0.187649 millimho. The same load of $B'' b'' = 1000$ ohms is permanently attached to the B'' terminal.

It is readily possible to substitute for the dissymmetrical T a, o, b , of Fig. 8, the terminally loaded smooth line of Fig. 10, in any steady-state system. The smooth line is readily dealt with in computation, and the permanent load $B'' b''$ merely modifies the conditions existing at B , in a manner deducible directly from Ohm's law. If preferred, the load may be dealt with by assigning to it an auxiliary angle θ' ; so that the position angle at a , becomes $\theta + \theta'$.

Although the reduction to symmetry effected by reducing the higher-impedance branch of the T to equality with the lower-impedance branch, is perhaps the simplest, especially in a continuous-current case like that of Fig. 8; yet it is by no means the only method of procedure open to use. Thus, the dissymmetrical T of Fig. 8, might be replaced by its corresponding dissymmetrical equivalent π , as in Figs. 11 and 12. The π , $a' b' g' h'$ of Fig. 12 may be reduced to symmetry, by cutting off part of the leak $a' g'$ as a terminal load, and leaving the remainder at $a'' G$, Fig. 13, equal to the leak $b'' h''$. This leaves the symmetrical π , $a'' b'' G h''$, of angle $\theta = 0.622362$ and surge impedance $z_0 = 5125.67$ ohms, but with the leak $a'' g''$ of 0.058824 millimho permanently attached to a'' . This symmetrical π might now be replaced either by a leak-loaded symmetrical T , or by a smooth line with the same terminal leak load.

Again it would be possible to reduce the T of Figs. 8 and 11 to symmetry, by employing permanent pairs of unequal terminal series loads, as for instance 100 ohms at a , and 1100 ohms at b , so as to produce a symmetrical T with 900 ohms in each branch. This

could be done in an infinite number of ways, each giving a different θ , a different z_0 , and a different pair of permanent terminal loads. It would also be possible to reduce the π of Fig. 12 to symmetry, by employing pairs of unequal terminal leak loads. There would be an infinite number of such possible pairs, with corresponding values of θ and z_0 . Consequently, a dissymmetrical network admits of being reduced to symmetry for computation, in one way with a single ter-

FIGS. 11, 12 AND 13. DISSYMMETRICAL T REPLACED BY ITS CORRESPONDING DISSYMMETRICAL π , WHICH IS REDUCED TO SYMMETRY BY THE RETENTION OF A PERMANENT LEAK AT THE a'' TERMINAL.

minal series load, in one way with a single terminal leak load, in an infinite number of ways with a pair of opposite terminal series loads, and also in an infinite number of ways with a pair of opposite terminal leak loads. In practise, the two single-load methods are preferable and easier to use.

(2) *The Method of Applying the Inequality Ratio q .* In this method, the system is left in its dissymmetrical state; but measurements are made from each pair of terminals in turn, to determine the apparent surge impedance from each end.

Returning to the dissymmetrical T of Figs. 8 and 11, we can measure the resistance R_a , offered between the terminal a and the return conductor or ground g , when

the system is freed or opened at the opposite terminals b, h . We may also measure the resistance R_{ag} offered between the same terminals at a , when the end b is grounded, or the terminals b, h are short-circuited. Following the usual rule for finding the angle of a symmetrical smooth line, the apparent angle of the system is expressed by:

$$\tanh \theta = \sqrt{R_{ag}/R_{af}} \quad \text{numeric } \angle \quad (1)$$

In the particular case of Fig. 8, the resistance R_{ag} would be 2428.57 ohms, and $R_{af} = 6000$ ohms, from which $\tanh \theta = 0.636209$ and $\theta = 0.751779$ hyp. ra-

FIG. 14—NETWORK OF FIG. 11 WITH SINGLE ANGLE θ , BUT WITH SURGE IMPEDANCES z_{0a} AND z_{0b} AS DETERMINED FROM EACH END.

dians. Similarly, according to the regular rule for a symmetrical line, the apparent surge impedance z_{0a} from the end a , is

$$z_{0a} = \sqrt{R_{af} \cdot R_{ag}} \quad \text{ohms } \angle \quad (2)$$

which in the case considered, is 3817.26 ohms. If now we repeat the measurements from the b end, successively freeing and grounding the a terminal, we find R_{bf} and R_{bg} , which would be 7000 and 2833.33 ohms respectively. As before,

$$\tanh \theta = \sqrt{R_{bg}/R_{bf}} = 0.636209 \quad \text{numeric } \angle \quad (3)$$

whence $\theta = 0.751779$. This is the same value as was found by (1), from the measurements at a . We may express this relation as a general rule thus: If in any dissymmetrical network of conductors, such as that of Fig. 7, we take two pairs of terminals like a, g , and b, h , and measure, at an assigned frequency, the impedance offered by the network between each pair, with the opposite pair first opened and then shorted, we may denote these impedances by R_{af} , R_{ag} and R_{bf} , R_{bg} , ohms $\angle$ respectively. Then the ratios R_{ag}/R_{af} and R_{bg}/R_{bf} will be equal to each other, and to the square of the tangent of the angle subtended by the network with respect to those four terminals.

On the other hand, if the network is dissymmetrical, the apparent surge impedance from b , or

$$z_{0b} = \sqrt{R_{bf} \cdot R_{bg}} \quad \text{ohms } \angle \quad (4)$$

will not be the same as z_{0a} . In the case considered, $z_{0b} = 4453.46$ ohms. The geometrical mean z_{ab} of the two opposite apparent surge impedances is defined by

$$z_{ab} = \sqrt{z_{0a} \cdot z_{0b}} \quad \text{ohms } \angle \quad (5)$$

is a characteristic property of the network, in this case 4123.11 ohms. It may be called the "geomean surge impedance" of the network.

The ratio of the a -end surge impedance z_{0a} to the geomean surge impedance z_{ab} may be called q , the

"inequality ratio" of the system. It will be defined by:

$$q = z_{0a}/z_{ab} = \sqrt{R_{ag}/R_{bg}} = \sqrt{R_{af}/R_{bf}} = \sqrt{z_{0a}/z_{0b}} \\ = \sqrt{\frac{\rho_1 + \alpha}{\rho_2 + \alpha}} = \sqrt{\frac{g_2 + \nu}{g_1 + \nu}} \quad \text{numeric } \angle \quad (6)$$

In this case the inequality ratio is $q = 0.92582$.

We may thus represent either the dissymmetrical T of Fig. 11, or its corresponding π of Fig. 12, by the dissymmetrical line system of Fig. 14. Here the line a, b , is to be regarded as a composite line, offering the same angle from each end, but different surge impedances.

Terminal Potentials and Currents in a Dissymmetrical System. If we have any physically consistent distributions of potential, current and power at the a and b terminals of a known dissymmetrical system, and we know the values of potential and current at one end, we can readily ascertain the corresponding values at the other, for one and the same frequency.

In the case of Fig. 15, we have the same dissymmetrical system as in Figs. 11, 12 and 14, for which θ , z_{0a} and z_{0b} are given. A potential of 1.0 volt and an entering current of $I_a = 0.347826$ milliamperes, are found at the generating end a . Required the cor-

FIGS. 15 AND 16—NETWORK LOADED WITH A TERMINAL IMPEDANCE σ AT EACH END ALTERNATELY

responding values at the motor end b . The value of the load σ at b need not be known. We have then:

$$E_b = \frac{1}{q} (E_a \cosh \theta - I_a z_{0a} \sinh \theta) \quad \text{volts } \angle \quad (7)$$

and $I_b = q (I_a \cosh \theta - E_a y_{0a} \sinh \theta)$ amperes $\angle$ (8) where $y_{0a} = 1/z_{0a}$, is the surge admittance, as measured from a . If $q = 1$; so that the dissymmetry is made to disappear, the above formulas are those which apply

to any ordinary smooth line of θ and z_0 . In the case considered, $E_b = 0.21739$ volt, and $I_b = 0.21739$ milliampere.

If on the contrary, we know E_b and I_b only, without necessarily knowing the physical conditions at the motor terminal b , we may proceed to find the corresponding values at the generator end a . We obtain:

$$E_a = q (E_b \cosh \theta + I_b z_{0b} \sinh \theta) \quad \text{volts } \angle \quad (9)$$

$$\text{and } I_a = \frac{1}{q} (I_b \cosh \theta + E_b y_{0b} \sinh \theta) \quad \text{amperes } \angle \quad (10)$$

where $y_{0b} = 1/z_{0b}$ is the surge admittance as measured at b . If we make $q = 1$, these formulas become identical with those pertaining to a simple smooth line and symmetrical system. In any such smooth-line case, formulas like (7), (8), (9) and (10) can be employed for any point along the line; but in the case of a dissymmetrical system, they apply only to the terminals a and b .

Again, if b is the generator end, and a the motor end of the dissymmetrical system, (see Fig. 16); and we know the potential E_a and current I_a , at a , we can find the corresponding values at b as follows:

$$E_b = \frac{1}{q} (E_a \cosh \theta + I_a z_{0a} \sinh \theta) \quad \text{volts } \angle \quad (11)$$

$$I_b = q (I_a \cosh \theta + E_a y_{0a} \sinh \theta) \quad \text{amperes } \angle \quad (12)$$

Similarly, if we know the generator-end values, E_b and I_b , the corresponding motor-end values E_a and I_a become:

$$E_a = q (E_b \cosh \theta - I_b z_{0b} \sinh \theta) \quad \text{volts } \angle \quad (13)$$

$$I_a = \frac{1}{q} (I_b \cosh \theta - E_b y_{0b} \sinh \theta) \quad \text{amperes } \angle \quad (14)$$

Here again, if $q = 1$, the formulas are those which apply at the terminals of a smooth line and symmetrical system. Hence we may formulate the following rule for any dissymmetrical case. Having given the potential and current at one end, write the corresponding values for the other, with regard to the direction of power transmission, as though the line were smooth and the system symmetrical. Use the surge impedance or admittance belonging to the end at which the values are known. Then an unknown potential E_a at a , will be $q = \sqrt{z_{0a}/z_{0b}}$ times that found by the regular formula, and likewise an unknown current I_b at b . On the other hand, an unknown current I_a at a , or a potential E_b at b , will be $1/q$ times that found by the regular smooth-line formula. The power products $E_a I_a$, and $E_b I_b$ will therefore not differ from those given by the corresponding smooth-line formulas.

Position Angles at the Terminals of a Dissymmetrical System. If we load the motor end b of a dissymmetrical system, like that of Fig. 15, with an impedance σ ohms $\angle$, we may find the position angle of that end in the same manner as though the load were applied to the motor end of a simple smooth line; *i. e.*

$$\tanh \delta_b = \sigma/z_{0b} \quad \text{numeric } \angle \quad (15)$$

Thus in Fig. 15, the position angle δ_b at b is 0.228437 hyp. The position angle δ_a at the generator end a is then obtained by the usual rule:

$$\delta_a = \theta + \delta_b \quad \text{hyp } \angle \quad (16)$$

which in this case is 0.980217 hyp. The potentials and currents at the ends of the dissymmetrical system are then related as follow:

With E_b and I_b known,

$$E_a = q \left(E_b \frac{\sinh \delta_a}{\sinh \delta_b} \right) \quad \text{volts } \angle \quad (17)$$

$$I_a = \frac{1}{q} \left(I_b \frac{\cosh \delta_a}{\cosh \delta_b} \right) \quad \text{amperes } \angle \quad (18)$$

The impedance beyond b is σ . The impedance at a is:

$$Z_a = z_{0a} \tanh \delta_a \quad \text{ohms } \angle \quad (19)$$

The power at a is the local product of E_a and I_a in vector watts, according to the regular rule.

With E_a and I_a known,

$$E_b = \frac{1}{q} \left(E_a \frac{\sinh \delta_b}{\sinh \delta_a} \right) \quad \text{volts } \angle \quad (20)$$

$$I_b = q \left(I_a \frac{\cosh \delta_b}{\cosh \delta_a} \right) \quad \text{amperes } \angle \quad (21)$$

Formulas (17) to (21) apply to ordinary smooth-line symmetrical systems, if $q = 1$. Whereas, however, in a smooth-line system, a position angle can be assigned to each and every point of the line, we are only justified in assigning position angles to two points—the a and b ends—of a dissymmetrical system.

Similarly, if b is the generator end (Fig. 16) and a the motor end of a dissymmetrical system, to which a load σ is applied, the position angle at a is defined by:

$$\tanh \delta_a = \sigma/z_{0a} \quad \text{numeric } \angle \quad (22)$$

In the case considered, $\delta_a = 0.268221$ hyp. The position angle at b is:

$$\delta_b = \theta + \delta_a \quad \text{hyp } \angle \quad (23)$$

The potentials and currents at the two ends are thus related:

With E_b and I_b known,

$$E_a = q \left(E_b \frac{\sinh \delta_a}{\sinh \delta_b} \right) \quad \text{volts } \angle \quad (24)$$

$$I_a = \frac{1}{q} \left(I_b \frac{\cosh \delta_a}{\cosh \delta_b} \right) \quad \text{amperes } \angle \quad (25)$$

With E_a and I_a known,

$$E_b = \frac{1}{q} \left(E_a \frac{\sinh \delta_b}{\sinh \delta_a} \right) \quad \text{volts } \angle \quad (26)$$

$$I_b = q \left(I_a \frac{\cosh \delta_b}{\cosh \delta_a} \right) \quad \text{amperes } \angle \quad (27)$$

The impedance at the generator end is:

$$Z_b = z_{0b} \tanh \delta_b \quad \text{ohms } \angle \quad (28)$$

Formulas (24) to (27) are identical with (17), (18) and (20), (21).

We may formulate the deductions from the last 13 formulas as follow: In any dissymmetrical system for which θ , z_{0a} and z_{0b} are given, and which is loaded at the

motor end with an impedance σ , find the position angle at the motor end, with reference to that end's surge impedance. If the potential and current are given at one end of the system, the values at the other end are found by using the ordinary position-angle formulas for a smooth line. An unknown E_a , or I_b , will then be $q = \sqrt{z_{0a}/z_{0b}}$ times the value so obtained. On the other hand, an unknown E_b or I_a , will be $1/q$ times the value obtained by the ordinary formula. This rule agrees with that given above for use with formulas (7) to (14).

In view of the above mentioned reciprocal factors for potential and current at each terminal, leaving the power products unchanged, it becomes possible to reduce a dissymmetrical system to a corresponding symmetrical system plus a terminal ideal transformer, without losses, and with a transformation ratio of q . It is doubtful, however, there would be any advantage in this plan over the method above outlined.

In the case of an actual composite line, like that of Fig. 4, with definite sections, having respective angles $\theta_1, \theta_2, \theta_3, \dots$ and surge impedances $z_{01}, z_{02}, z_{03}, \dots$, it is advantageous to work up the position angles at the successive terminals commencing with the motor end. The terminal position angle at a would thus become δ_1 , with a terminal surge impedance z_{01} ; while working from the other end, the terminal position angle would be δ_n , with a terminal surge impedance of z_{0n} . The impedance R_{ag} as measured at a would be

$$R_{ag} = z_{01} \tanh \delta_1 \quad \text{ohms } \angle \quad (29)$$

while that measured at b would be

$$R_{bg} = z_{0n} \tanh \delta_n \quad \text{ohms } \angle \quad (30)$$

These values are not inconsistent with (19) and (28), which pertain to a general network; whereas (29) and (30) pertain to a particular composite line with detailed sections.

Receiving-End Impedance of a Dissymmetrical Network. If we define this quantity as the ratio of the e. m. f. impressed at the generator terminals to the current received through a load connecting the motor terminals, we find that for a load σ at b , (Fig. 15), the receiving end impedance is:

$$Z_{ib} = q (z_{0b} \sinh \theta + \sigma \cosh \theta) \quad \text{ohms } \angle \quad (31)$$

In the case represented in Fig. 15, $Z_{ib} = 4600.0$ ohms. When $q = 1$, this expression reduces to the ordinary value $z_0 \sinh \theta + \sigma \cosh \theta$, for a simple smooth line or symmetrical system.

When $\sigma = 0$, or the b terminals are short-circuited, (31) becomes:

$$Z_{ib} = q z_{0b} \sinh \theta = z_{ab} \sinh \theta \quad \text{ohms } \angle \quad (32)$$

which is the architrave impedance in Fig. 12, or 3400.0 ohms.

Similarly, for a load of σ ohms $\angle$ at the motor end a , the receiving-end impedance becomes (Fig. 16.)

$$Z_{ia} = \frac{1}{q} (z_{0a} \sinh \theta + \sigma \cosh \theta) \quad \text{ohms } \angle \quad (33)$$

In the case of Fig. 16, this becomes 4800.0 ohms.

When $q = 1$, the expression (33) again coincides with the ordinary smooth-line formula. Moreover, when $\sigma = 0$,

$$Z_{ia} = \frac{1}{q} (z_{0a} \sinh \theta) = z_{ab} \sinh \theta \quad \text{ohms } \angle \quad (34)$$

or 3400.0 ohms, the architrave impedance of the equivalent dissymmetrical π .

We may formulate these results as follows. The receiving-end impedance of a dissymmetrical network loaded at the receiving end, is found by the usual rule

FIG. 17—DISSYMMETRICAL T OF IMPEDANCE REPRESENTING A NETWORK OF ALTERNATING-CURRENT CONDUCTORS

for a terminally loaded smooth line, using the surge impedance of the motor end. The result must then be multiplied by q , when the generator is at a , and by $1/q$ when the generator is at b . In case the load is short-circuited, the receiving-end impedance reduces to $\rho'' = z_{ab} \sinh \theta$, the architrave impedance of the equivalent dissymmetrical π .

Technique of Measurements. We have assumed that the measurements made on the network are the four terminal impedances R_{af} , R_{ag} , R_{bf} , and R_{bg} . In cases where there is but little difference between R_{af} and R_{ag} ,

FIG. 18—DISSYMMETRICAL EQUIVALENT π OF SAME

or between R_{bf} and R_{bg} , the value of θ may not admit of being determined with satisfactory precision; although the value of z_{ab} will usually be acceptable. In such a case, if the two ends of the network can be brought to the same testing table, it may be preferable to adopt the following technique:

1. Measure, with b open, the impedance R_{af} ohms at a , and the entering current I_a at a . At the same time measure the vector p. d. e_b volts thereby produced at the b terminals. From these data, ρ_1 and α can be deduced.

2. Measure R_{ag} ohms $\angle$ at a . With this value and R_{af} , find z_{oa} , by (2).

3. Repeat the measurements (1) and (2) reciprocally with the ends of the network reversed, so as to obtain R_{bf} , e_a and R_{bg} . These will give ρ_2 and z_{ob} , together with check values of θ and α .

Example of a Dissymmetrical Alternating-Current System. Fig. 17 offers a particular dissymmetrical

$$\begin{aligned} R_{af} &= 5385.17 \angle 21^\circ 48' 5'' = 5000 - j2000^\omega & R_{bf} &= 6946.22 \angle 30^\circ 15' 23'' = 6000 - j3500^\omega \\ R_{ag} &= 2435.70 \angle 11^\circ 17' 10'' = 2388.6 + j476.68^\omega & R_{bg} &= 3141.77 \angle 2^\circ 49' 52'' = 3137.93 + j155.17^\omega \end{aligned}$$

FIG. 19—NETWORK OF FIG. 17 WITH SINGLE ANGLE θ , BUT WITH SURGE IMPEDANCES z_{oa} AND z_{ob} AS DETERMINED FROM EACH END.

T system, which might be the equivalent of a certain network between the two pairs of terminals a, g and b, h . The impedance ao , is $1000 + j1000$ ohms, such as might be produced by an inductor of 0.1 henry and 1000 ohms, at an angular velocity of $\omega = 10000$ radians per second, ($1591.5 \sim$). The impedance ob is $2000 - j500$ ohms, such as might be produced at the same frequency by a condenser of 0.2 microfarad, in series with 2000 ohms. The impedance

FIG. 20—SAME WITH TERMINAL LOAD AT b

og is $4000 - j3000$ ohms. The equivalent π of this system is given in Fig. 18, and the equivalent composite line network in Fig. 19. The angle subtended by the network is $\theta = 0.705768 + j0.305124$ hyphs; or quadranting the imaginary part $\theta = 0.705768 + j0.194248$ hyphs. The functions of this angle are:

$$\begin{aligned} \sinh \theta &= 0.822652 \angle 27^\circ 23' 05'' \\ \cosh \theta &= 1.223218 \angle 10^\circ 50' 28'' \\ \tanh \theta &= 0.672531 \angle 16^\circ 32' 37'' \end{aligned}$$

Many of the formulas in Appendix A can be checked from Figs. (17), (18) and (19) by an inspection of the slopes of the various complex quantities presented.

In Fig. 20, the system of Figs. (17), (18) and (19) is represented as being loaded at the b end with $\sigma = 3516.03 + j14409.4$ ohms, and supplied at the a end with an e. m. f. of 1.0 $\angle 0^\circ$ volt at the frequency of reference. The terminal position angles, potentials and currents are marked on the Figure, in accordance with formulas (15) to (21).

In Appendix A, a number of formulas have been collected relating to dissymmetrical networks and their equivalent circuits. The notation is in accordance with Figs. 21 and 22, and the numerical values pertain to the particular case of Figs. 14, 15 and 16.

FIGS. 21 AND 22—DISSYMMETRICAL T AND π WITH THEIR ELEMENTS SYMBOLIZED, ALSO NUMERICAL VALUES CONFORMING WITH THE PARTICULAR CASE OF FIGS. 11, 12 AND 14.

In Appendix B, a corresponding series of formulas has been collected, relating to symmetrical networks and their equivalent circuits; *i. e.*, for the case $q = 1$. The notation is in accordance with Figs. 23, 24 and 25. The numerical values pertain to the system having the same θ as in Figs. 14, 15 and 16 and with its surge impedance z_a equal to the geometric surge impedance z_{ab} of the dissymmetrical system. The values of R_f and R_g in this case are respectively the geometric values of R_{af} , R_{bf} and R_{ag} , R_{bg} .

We have considered, in all of the cases represented by the figures, that in any dissymmetrical T , all of the series impedance is lodged in the conductor a, o, b , and that the return conductor g, h , has negligible impedance. According to the known theory of T conductors, however, any desired share of series impedance can be transferred from a, o, b , to g, h , without disturbing the e. m. fs., currents and powers at and

beyond the system terminals, provided that the total series impedance on the a side of the leak $o q$ is constant, and likewise the total series impedance on the b side. In other words a T -system may be converted into a H -system.

Similarly, although in all the π -systems indicated in the Figures, all the series impedance is lodged in the conductor a', b' ; yet any desired share of this impedance may be transferred to g', h' , without disturbing the e. m. fs., currents and powers at and beyond the

z_0 , and a single terminal load, which may be treated as having an auxiliary angle θ' .

2. Any such dissymmetrical network may also be regarded as possessing and being defined by (a) an angle θ , (b) a geometric surge impedance z_{ab} , and (c) an inequality ratio q . The electric behavior of the network, at the assigned frequency, with respect to the two pairs of terminals, may then be computed by the usual formulas applying to a simple smooth line; but with the further application of the coefficient q .

3. The theory of simple alternating-current lines with smoothly distributed constants may thus be regarded as being a particular case ($q = 1$) of the general theory of dissymmetrical networks having any degree of complexity.

LIST OF SYMBOLS EMPLOYED

$\delta_a, \delta_b,$	position angles at a and b ends of a diss. network (hypos $\angle$).
δ_1, δ_n	position angles at ends of a detailed composite line (hypos $\angle$).
E_a, E_b	e. m. fs. applied to a and b ends of a diss. network (volts $\angle$).
$e_a, e_b,$	p. d. s. at open a and b ends of diss. network by application of a testing e. m. f. at the opposite end (volts $\angle$).
f	frequency applied to network (cycles per second).
G	total conductance of a smooth sym. line (mhos $\angle$).
$G_a, G_b,$	admittance of a sym. system, when respectively freed and grounded at the other end (mhos $\angle$).
$G_{af}, G_{ag},$	admittance of a diss. system, at the a end, when respectively freed and grounded at the other end (mhos $\angle$).
$G_{bf}, G_{bg},$	admittance of a diss. system, at the b end, when respectively freed and grounded at the other end (mhos $\angle$).
g	admittance of leak in equiv. T of a diss. system (mhos $\angle$).
$g_1, g_2,$	admittances of leaks at a and b ends in equiv. π of a diss. system (mhos $\angle$).
g'	admittance of leak in equiv. T of a sym. system (mhos $\angle$).
g''	admittance of each leak in equiv. π of a sym. system (mhos $\angle$).
θ	angle subtended by a line or system (hypos $\angle$).
θ'	angle subtended by a terminal load (hypos $\angle$).
$\theta_1, \theta_2, \dots \theta_n$	angles subtended by successive sections of a composite line (hypos $\angle$).
$I_a, I_b,$	current strengths at ends of a network (amperes $\angle$).
$j = \sqrt{-1}$	
ν	series adm. of a sym. or diss. π (mhos $\angle$).
$q = \sqrt{z_{0a}/z_{0b}}$	inequality ratio of a diss. network (numeric $\angle$).

FIGS. 23, 24 AND 25—SYMMETRICAL T , π AND SMOOTH LINE HAVING THE SAME ANGLE FEEDER AS IN FIGS. 14, 21 AND 22, ALSO WITH $z_0 = z_{ab}$ OF THE DISSYMMETRICAL CASE.

system terminals. In other words, the dissymmetrical π s may be converted into corresponding O -systems.

SUMMARY OF CONCLUSIONS

1. Any dissymmetrical conducting network, each element of which obeys Ohm's law generalized for alternating currents, may be reduced to symmetry, with respect to two pairs of terminals, and at an assigned frequency, either by finding its equivalent T and equating the two arms, through the medium of a permanent series terminal load; or, by finding its equivalent π and equating the two pillars, through the medium of a permanent terminal leak load. The system then offers a certain angle θ , a surge impedance

R	total conductor resistance of a smooth line (ohms $\angle$).	$Z_a, Z_b,$	generator-end impedances of a diss. system (ohms $\angle$).
$R_f, R_g,$	impedance at one end of a sym. system, when the other end is freed and grounded respectively (ohms $\angle$).	$Z_{fa}, Z_{fb},$	receiving-end impedances of a diss. system, including load (ohms $\angle$).
$R_{af}, R_{ag},$	impedance at the a end of a diss. system when the other end is freed and grounded respectively (ohms $\angle$).	$z_0,$	surge impedance of a sym. system (ohms $\angle$).
$R_{bf}, R_{bg},$	impedance at the b end of a diss. system, when the other end is respectively freed and grounded (ohms $\angle$).	$z_{0a}, z_{0b},$	surge impedance at a and b ends of a diss. system (ohms $\angle$).
$\mathcal{R}$	impedance of leak in equiv. T of a diss. system (ohms $\angle$).	$z_{ab} = \sqrt{z_{0a} z_{0b}}$	geomean surge impedance of a diss. system (ohms $\angle$).
$\mathcal{R}_1, \mathcal{R}_2,$	impedances of a and b leaks in the equiv. π of a diss. system (ohms $\angle$).	$z_{01}, z_{02}, \dots z_{0n}$	surge impedances of successive sections in composite line (ohms $\angle$).
$\mathcal{R}'$	impedance of leak in equiv. T of a sym. system (ohms $\angle$).	$\omega = 2 \pi f$	angular velocity of frequency impressed on a system (rad. per sec.)
$\mathcal{R}''$	impedance of each leak in equiv. π of a sym. system (ohms $\angle$).	$\sim$	sign for "cycles per second."
ρ	impedance of architrave in equiv. π of a diss. system (ohms $\angle$).	$\angle$	sign for a complex numerical quantity.
$\rho_1, \rho_2,$	impedance of a and b arms in equiv. T of a diss. system (ohms $\angle$).	hyp.	abbreviation for "hyperbolic radian."
ρ'	impedance of each arm in equiv. T of a sym. system (ohms $\angle$).		
ρ''	impedance of architrave in equiv. π of a sym. system (ohms $\angle$).		
σ	impedance of a load at motor end of a system (ohms $\angle$).		
y_0	surge admittance of a sym. system (mhos $\angle$).		
$y_{0a}, y_{0b},$	surge admittance at a and b ends of a diss. system (mhos $\angle$).		
$y_{ab} = \sqrt{y_{0a} y_{0b}}$	geometrical mean surge admittance of a diss. system mhos $\angle$).

APPENDIX A

List of formulas applicable to a dissymmetrical T , π or Network. The numerical values pertain to the case of Figs. 17, 18, 21 and 22.

$$\frac{R_{ag}}{R_{af}} = \frac{R_{bg}}{R_{bf}} = \frac{G_{af}}{G_{ag}} = \frac{G_{bf}}{G_{bg}} = \frac{\mathcal{R}(\rho_1 + \rho_2) + \rho_1 \rho_2}{(\mathcal{R} + \rho_1)(\mathcal{R} + \rho_2)} = \frac{\nu(g_1 + g_2) + g_1 g_2}{(\nu + g_1)(\nu + g_2)} = \tanh^2 \theta$$

$$= 0.404762 \quad \text{numeric } \angle \quad (35)$$

$$\frac{\rho_1}{\rho_2} = \frac{g_2}{g_1} = \frac{\mathcal{R}_1}{\mathcal{R}_2} = \frac{q \cosh \theta - 1}{\frac{1}{q} \cosh \theta - 1} = 0.5 \quad \text{numeric } \angle \quad (36)$$

$$q = \sqrt{R_{ag}/R_{bg}} = \sqrt{R_{af}/R_{bf}} = \sqrt{G_{bg}/G_{ag}} = \sqrt{G_{bf}/G_{af}} = \sqrt{z_{0a}/z_{0b}} = \sqrt{\frac{\rho_1 + \mathcal{R}}{\rho_2 + \mathcal{R}}} = \sqrt{\frac{g_2 + \nu}{g_1 + \nu}}$$

$$= z_{0a}/z_{ab} = 0.92582 \quad \text{numeric } \angle \quad (37)$$

$$1/q = \sqrt{R_{bg}/R_{ag}} = \sqrt{R_{bf}/R_{af}} = \sqrt{G_{ag}/G_{bg}} = \sqrt{G_{af}/G_{bf}} = \sqrt{z_{0b}/z_{0a}} = \sqrt{\frac{\rho_2 + \mathcal{R}}{\rho_1 + \mathcal{R}}} = \sqrt{\frac{g_1 + \nu}{g_2 + \nu}}$$

$$= z_{0b}/z_{ab} = 1.08012 \quad \text{numeric } \angle \quad (38)$$

$$\frac{\frac{1}{2}(\rho_1 + \rho_2)}{\mathcal{R}} = \frac{\frac{1}{2}(g_1 + g_2)}{\nu} = \left(\frac{q + 1/q}{2} \right) \cosh \theta - 1 = 0.3 \quad \text{numeric } \angle \quad (39)$$

$$\frac{\sqrt{\rho_1 \rho_2}}{\mathcal{R}} = \frac{\sqrt{g_1 g_2}}{\nu} = \sqrt{(q \cosh \theta - 1) \left(\frac{1}{q} \cosh \theta - 1 \right)} = 0.28284 \quad \text{numeric } \angle \quad (40)$$

$$\begin{aligned}
\rho_1/g_2 &= \rho_2/g_1 = \rho_1 \mathcal{R}_2 = \rho_2 \mathcal{R}_1 = \rho \mathcal{R} = \rho/g = \mathcal{R}/\nu = \sqrt{\frac{\rho_1 \rho_2}{g_1 g_2}} = z_{0a} z_{0b} = z_{ab}^2 = R_{af} R_{bg} \\
&= R_{ag} R_{bf} = \rho_1 \rho_2 + \mathcal{R} (\rho_1 + \rho_2) = \sqrt{R_{af} R_{ag} R_{bf} R_{bg}} = \sqrt{\rho_1 \rho_2 \mathcal{R}_1 \mathcal{R}_2} \\
&= \sqrt{\{\rho_1 (\rho_2 + \mathcal{R}) + \rho_2 \mathcal{R}\} \{\rho_2 (\rho_2 + \mathcal{R}) + \rho_1 \mathcal{R}\}} = 17,000,000 = (4123.106)^2 \text{ ohms}^2 \angle \quad (41)
\end{aligned}$$

$$\begin{aligned}
g_1/\rho_2 &= g_2/\rho_1 = \nu g = g/\rho = \nu/\mathcal{R} = \sqrt{\frac{g_1 g_2}{\rho_1 \rho_2}} = y_{0a} y_{0b} = y_{ab}^2 = G_{af} G_{bg} = G_{ag} G_{bf} \\
&= g_1 g_2 + \nu (g_1 + g_2) = \sqrt{G_{af} G_{ag} G_{bf} G_{bg}} = \sqrt{\{g_1 (g_2 + \nu) + g_2 \nu\} \{g_2 (g_1 + \nu) + g_1 \nu\}} \\
&= 0.058824 \times 10^{-6} = (0.2425355 \times 10^{-3})^2 \text{ mhos}^2 \angle \quad (42)
\end{aligned}$$

$$z_{0a} = \sqrt{R_{af} R_{ag}} = \sqrt{\rho_1 (\rho_1 + \mathcal{R}) + \rho_2 \mathcal{R} \frac{\rho_1 + \mathcal{R}}{\rho_2 + \mathcal{R}}} = q z_{ab} = q^2 z_{0b} = 3817.26 \text{ ohms} \angle \quad (43)$$

$$z_{0b} = \sqrt{R_{bf} R_{bg}} = \sqrt{\rho_2 (\rho_2 + \mathcal{R}) + \rho_1 \mathcal{R} \frac{\rho_2 + \mathcal{R}}{\rho_1 + \mathcal{R}}} = \frac{1}{q} z_{ab} = \frac{1}{q^2} z_{0a} = 4453.46 \text{ ohms} \angle \quad (44)$$

$$\begin{aligned}

Discussion

F. S. Dellenbaugh, Jr.: The extreme simplicity with which complex circuits may be worked down to a simple circuit is really extraordinary. As you will notice in the bibliography, Dr. Kennelly was the first to publish "The Equivalence of Triangles and Three-pointed Stars," in other words, star-delta transformations in 1899, and it has been a little over 23 years that this process has been known and published, and yet, commercially, it appears to be used very little.

I know a number of commercial cases that I have met with or heard of, that required a very long time, solving networks by the older methods and where, by the use of a star delta transformation, it could be solved immediately, without much effort. In one case, it took an engineer the better part of a day to calculate a circuit by the net work method, that is the older method of Kirchoff's Laws, and so forth, and a young engineer without much experience, but who happened to know this method of Dr. Kennelly's, did this same job in half an hour. The other method made a few approximations as well, while the latter method was accurate.

I think perhaps one trouble is due to the fact that when you have these formulas, the average man does not always know just what to do with them, and while the formulas come down to

a very simple looking result, you cannot find out how just to get the numerical answer. If you look it up you find that there are tables of these complex angles and you attempt to use the tables, and find for accurate work, that you have to interpolate. With angles of complex quantities in two dimensions, it is necessary to make six averages to get the final answer, which is laborious.

But in addition to those tables, Dr. Kennelly has prepared some very beautiful charts, and I never think of using the tables any more, because the charts are as accurate as ordinary slide rule work, and you have the very great advantage of seeing the way in which the functions change. Very often, in interpolating from the tables, there is a rapid rate of change, which may make considerable error in a straight line interpolation. Of course, you can use more accurate methods of interpolation, but it requires more time.

I want to make a plea for the use of this method. For those who find it difficult to get results, let them look at Dr. Kennelly's charts of hyperbolic functions, and once the system of going through those charts to find the functions is learned, you will find it is no more difficult to use hyperbolic functions of complex angles than ordinary formulas for the solution of triangles. It involves putting down a few more figures, but it is so much simpler and very much quicker than any method of Kirchoff's Laws, if you have more than the simplest kind of network.

Physical Interpretation of Complex Angles and Their Functions

BY ARAM BOYAJIAN

Member, A. I. E. E.
General Electric Co. Pittsfield, Mass.

Review of the Subject.—A child's idea of an angle is a corner or edge; the sharper the corner or edge, the smaller is the angle, and hence expressions like "acute (sharp) angle," "obtuse (blunt) angle," etc. With a little schooling his idea of an angle is broadened into that of turning or rotation and finds a geometrical expression in a circle. The amount of turning is represented by the area of the sector of the circle like a piece of pie gone over by the turning radius. This broadened idea is still in agreement with the earlier idea because the sector is a surface having a corner at the center of the circle, and the sharpness or bluntness of this corner varies with the area. With further progress, he also learns to associate the angle with the arc of the circle, for, evidently, the length of the arc is a measure of the amount of turning and is proportional to the area of the sector. The angle when represented by the arc of the circle loses all resemblance to a corner, which latter idea however is discarded as unnecessary, emphasis now being laid on "turning" which is well represented by the arc of the circle. Mathematical analysis is then applied which still further broadens the scope of angles and gives rise to the so called "imaginary" angles which are called "hyperbolic" in contrast with ordinary "real" angles which are called "circular," combinations of these two kinds of angles being called "general" or "complex." At this stage, any physical interpretation or geometrical representation of an angle practically vanishes, for, a hyperbolic angle can not be conceived of as a rotation, not even as a rotation around an "imaginary" axis, for, how can one conceive of an "imaginary" axis? If the "imaginary" axis be defined as a new axis at right angles to the old axis, rotation around it can easily be conceived of, but it does not correspond to facts, because a hyperbolic angle implies no change in direction, and hence no rotation, but merely affects the magnitude of a quantity. Inasmuch as problems can be solved mathematically without any visualization, the mathematician discards visual interpretations and bases his conceptions on formulas. However, the engineering type of mind finds it both difficult and distasteful to be dependent on symbolic definitions, and craves for visualization. He feels that if physical problems lead to "imaginary" or "complex" angles, these angles must stand for some concrete physical facts and must therefore be capable of a physical interpretation.

A broad and yet simple physical interpretation applicable to both circular and hyperbolic angles is developed below, which also applies to their trigonometric functions, as follows:

A quantity may be expressed or specified either by its own dimensions or as a percentage of another quantity. The first kind of specification is its "absolute" measure, the second kind is its "angular" measure. Thus "angle" and "percentage" are syn-

onymous terms. If a quantity changes by a certain percentage (compound percentage as in compound interest) that "percentage" is the "angular" change in the quantity in radians. According to this interpretation, neither corner, edge, turning nor rotation are essential characteristics of an angle; they are the characteristics of a limited class only. If the percentage change in a quantity is like itself, geometrically parallel to itself, the per cent change, that is, the angle, is called a hyperbolic angle, and there is no rotation. If the quantity varies without any change in magnitude but only with a change in direction, geometrically perpendicular to itself, the per cent change, that is, the angle, is called a circular angle, and there is rotation. Thus, hyperbolic and circular angles are at right angles to each other, the first being a per cent change parallel to the quantity, and the second perpendicular to it. "Imaginary" thus means a quadrature. However, it is not rotation around a quadrature axis but per cent change in a quadrature direction.

This new interpretation is in agreement with the representation by arcs in a more extended vectorial sense in which one is not limited to the arc of a circle but arcs of any shape have an angular interpretation. Thus, consider a portion of an arc of any arbitrary shape, and resolve it into two components, one circular (at right angles to the radius drawn to the point) and the other straight and radial (parallel to the radius at that point). These two arcs expressed as a percentage of the radius represent circular and hyperbolic angles, respectively, and being in quadrature with each other their vector sum is the "complex" angle of the arc. In this interpretation a hyperbola has nothing to do with a hyperbolic angle, and the name is unfortunate. It would have been more intelligible to speak of the ordinary circular angle as a "quadrature" angle, and of the so called hyperbolic angle as a "linear" angle or a "radial" angle.

This new interpretation of an angle is then utilized to interpret the physical significance of sines and cosines of angles, whether circular or hyperbolic. The common idea of a cosine as the projection of the radius vector on the X axis, and of sine as the projection on the Y axis, is found inadequate, this idea being limited to circular angles and not being of much value in explaining their occurrence in physical problems. A cosine is then interpreted as the mean vector value of a unit quantity for a given per cent increase and an equal per cent decrease, or a given value of rotation positive and negative. Examples are given illustrating the application of this vector idea in physical problems, as in the resolution of a harmonic wave into two oppositely rotating vectors, solution of differential equations, etc. A geometrical construction is given for the sines and cosines of complex angles, which is not merely a representation but photographically true, so to speak.

INTRODUCTION

THE student of trigonometric functions finds by some dark analytical transformations that the sines, cosines, etc., of imaginary angles are not impossible or absurd quantities but resolve themselves into hyperbolic functions of those angles looked upon

as real angles. Thus if θ is an "ordinary" angle, that is, a circular angle,

$$\cos(j\theta) = \cosh(\theta) \quad (1)$$

$$\sin(j\theta) = j \sinh(\theta) \quad (2)$$

$$\tan(j\theta) = j \tanh(\theta) \quad (3)$$

These identities indicate that a hyperbolic angle is j with respect to circular angles, and the questions naturally arise: (a) Wherein is a so-called hyperbolic angle an angle at all? (b) Wherein does it differ from ordinary angles? (c) What is the physical significance of its being j with respect to the ordinary angles?

1. All percentages, in this paper are supposed to carry their decimal points explicitly. Thus, ten per cent is to be given as 0.10, not merely as 10.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 14-17, 1923.

The usual representation of hyperbolic angles and functions by means of a hyperbola, as circular angles and their functions are represented by circles (See Figs. 1 and 2), completely fails to throw any light on these questions; the representation merely serving the purpose of giving an idea of their numerical values but not of their physical nature. Certainly, it is not evident from these figures wherein the area of the hyperbolic sector representing the hyperbolic angle is j with

Fig. 1

respect to the circular sector representing the circular angle. Furthermore, it is not evident wherein the hyperbolic sine and tangent are j with respect to the circular sine and tangent, while the hyperbolic cosine is "real" like the circular cosine. These points not being explainable on the basis of representation by a hyperbola, it is not to be expected that an explanation can be given on that basis of the physical significance

Fig. 2

of the so-called imaginary periodicity of hyperbolic functions, as in the equation

$$\cosh(\theta) = \cosh(\theta + 2\pi nj) \quad (4)$$

Evidently, we need first to develop a simple physical interpretation of what an angle is in its most general sense, a physical conception which will apply to hyperbolic angles as well as to circular angles and will show their natural relationship. Then we must develop a physical interpretation of trigonometric functions,

broad enough to include both types, and clear enough to show their relationship.

It will be shown below that an angle, in its broadest sense, is nothing more or less than a *percentage*, more specifically a percentage change in a quantity, the percentage being *compound* not simple percentage, effective at every point or instant, as for instance in compound interest. It will, then, be shown that an imaginary angle is nothing more or less than a quadrature angle, that is, one in quadrature with the circular angle. This is in accordance with the use of j in engineering as a quadrature operator, is consistent with the mathematics of hyperbolic trigonometry and leads to an extremely simple physical interpretation of the imaginary periodicity of hyperbolic functions, *viz.*, that their periodicity is not imaginary or unthinkable but in quadrature with themselves. The point of view is evidently vectorial. Since the arc represents the change in a vector vectorially, the component of the arc in quadrature with the vector represents the circular angle, the component parallel to the vector represents the hyperbolic angle, and the arc as such represents the complex angle. From this novel point of view all imaginariness disappears from the trigonometry of complex angles, and the various relationships usually established by tedious mathematical transformations become almost self-evident physical facts. We must therefore analyze this new interpretation in somewhat greater detail.

PHYSICAL MEANING OF AN ANGLE IN ITS BROADEST SENSE

Let the radius vector R move and trace an arbitrary curve, as shown in Fig. 3. On this curve consider any two adjacent points p_1 and p_2 . The arc between these two points represents the vector change in R and we shall designate it in the usual way as dR . Now, a radius vector can move or change in only two essentially different ways, *viz.*, (1) parallel to itself, stretching or shrinking, and, (2), at right angles to itself, rotating. Any other motion can be resolved into two such components, one parallel to the radius vector, the other in quadrature with it. In Fig. 3, the arc dR is resolved into two such components, dR_1 and dR_2 . It will be noted that the component at right angles to the radius vector is curved being the arc of a circle, as it must be to keep perpendicular to the radius vector at every successive position of the latter (See Fig. 4). However, if the path dR is taken short enough, dR_2 will be a straight line.² It is highly important to note that the two components, dR_1 and dR_2 of dR , are at right angles to each other.

The distance dR which the radius vector covers in its sweep along an arbitrary curve may be given in

2. At a later point in the discussion of angles in three dimensional space, a rigid physical and mathematical justification will be given why the vector angle is represented by the curved line and not by its chord.

and their functions are shown in their true physical nature and relationship.

It is to be observed that according to this new interpretation the characteristic which constitutes an angle is not *turning*, but just a *per cent change*, and therefore, it is not necessary to assume that hyperbolic angles are produced by the rotation of the radius vector around an "imaginary" axis in an "imaginary" plane as is sometimes suggested as explanation.

HOW TO CALCULATE THE ANGLE OF A PATH

When the radius vector R moves at right angles to itself, at every instant, its length is unchanged, and therefore, if we start with a radius vector of unit length, and let it trace a circle, the angle (dR/R)

Fig. 5

will always be equal to (dR) numerically. Therefore, in circular angles, the length of the arc is also a direct measure of the angle, but in hyperbolic angles, where the radius vector is moving parallel to itself and continually changing in length, the hyperbolic angle, (dR/R) , can not be represented by (dR) numerically. Hence, the scale of a hyperbolic angle continually changes.

Consider now a unit radius vector R along the X axis, (Fig. 5), and let it move along this axis generating a pure hyperbolic angle. Some time the radius vector will reach the point X . The question is, "What is the measure of hyperbolic angle which the path of the radius vector covers?" Or, in plainer language, what is the present change in the radius vector? Since the length of R has been changing every instant, we can not divide the length of path by the initial value of the radius vector, that is, unity, nor by the final value, but we must calculate the angle for very short intervals and add them. In calculus language, the hyperbolic angle described by the radius vector in its travel from 1 to X is

$$\theta = \int_1^x \frac{dx}{x} = L n^s(x) - L n(1) = L n(x) \quad (11)$$

This shows that the hyperbolic angle subtended by a straight line based on its initial portion of unit length is equal to its natural (or hyperbolic) logarithm, (and there is thus one reason why such an angle may be called hyperbolic), although, in referring to this feature, "logarithmic" angle may be a better name.

A few points of interest are to be noted in connection with equation (11) and Fig. (5).

(1) It will be seen that "natural log of path,"

3. We shall use $L n$ to designate natural logarithms, and "log" to designate ordinary decimal logarithms.

"angle covered by path" and "per cent length of path" are all equal and synonymous.

(2) The angles indicated are for a stretch of the radius vector from the point 1, *i. e.*, from the end of the unit radius vector, with which we started (not from O), to any desired point along its length. At the starting point, *i. e.*, at R equal to 1, the angle is zero. If the radius vector shrinks, instead of stretching, starting with a unit value, it generates a negative angle, which also is to be seen in Fig. 5.

(3) Due to the fact that the angle of the path is equal to the logarithm of the path, the positive angle increases very slowly as compared with the length of the path. Thus, when the radius vector or path is 10, the angle is 2.3 radians; but when the length is ten millions, the angle is only 23 radians (See Fig. 6).

(4) The reverse of what is true for positive angles is true for negative angles. Thus, the radius vector in shrinking from unity to zero generates an infinite negative angle (See Fig. 5).

(5) Ordinarily, it is not the angle at a point X (that is, between 1 and X) but between two points X_1 and X_2 which is desired, and which evidently is given by $L n(x_2) - L n(x_1)$.

(6) The radius vector is essentially positive, and, therefore, no matter in what direction it is drawn, it traces a positive angle if increasing, negative angle if decreasing, and therefore, it is impossible to get a negative radius vector or quantity, which also explains in a physical way the mathematical fact that "ordinary" logarithms do not apply to negative numbers. However, it is possible to transcend the "ordinary" even in the matter of logarithms as will be shown at a later point.

(7) Considering Fig. 6 it will be observed that the angle is graduated uniformly or arithmetically, whereas the radius vector or its path is graduated exponentially

Fig. 6

or geometrically with the object of covering a wide range, as in a slide-rule, the diagram corresponding to 2.3 unit length rule; the factor 2.3 arising from the ratio of ordinary logs to the natural logs. Though convenient for the purpose indicated, this scheme is not serviceable in every case, but the scheme of Fig. 5, in which the radius vector is graduated uniformly and the angle logarithmically, is applicable universally, as will be noted particularly in deriving the trigonometric functions of complex angles.

Before proceeding to the analysis of somewhat more involved aspects of the subject, it may be profitable at this point to tabulate the substance of the foregoing analysis both in every day and in mathematical language in two parallel columns for convenient comparison and greater intelligibility.

AN EXPOSITION OF ANGLES IN GENERAL

IN MATHEMATICAL ENGLISH

1. Let the radius vector R describe an arbitrary path.
2. The path divided by the radius vector is the angle in radians subtended by the path at the radius vector.

3. Any portion of the path may be resolved into two components, one parallel to the radius vector, the other perpendicular to it.

4. The "in phase" component of path divided by the radius vector is the hyperbolic angle in radians.

5. The angle generated by the radius vector per unit of time is called its "angular velocity" in radians. This applies to all kinds of angles, whether hyperbolic, circular, or the combination of the two, that is, general or complex.

6. If the path of the radius vector is at right angles to itself the path is then circular and expressed as a fraction of the radius vector is called a "circular angle" in radians. The circular angle (path) being perpendicular to the radius vector, is therefore perpendicular to the hyperbolic angle (path) which is parallel to the radius vector.

7. The angle which the rotating radius vector tends to produce per unit of time is called its angular velocity in radians per unit of time, as covered in art. 5.

IN EVERY DAY ENGLISH

1. Let a quantity R undergo any arbitrary change.

2. The change in the quantity R divided by R is a fraction and gives the change as a percentage of R . A per cent change is called angular change in mathematics.

3. The change, or per cent change, in R may be one of magnitude only, or it may be one of direction only. A general change may imply a certain per cent change in magnitude and a certain per cent change in direction.

4. A per cent change in magnitude has different names in practise, such as, *per cent (compound) interest* in banking; *per cent discharge* in hydraulics; *per cent decay* in electrical and radioactive problems; and, in general, as "per cent gain," or *per cent loss*. These percentages are called "hyperbolic angles," in mathematics. One hundred per cent is considered the unit of angles and is called one radian.

5. The per cent change which is produced per unit of time is called the "per cent rate of change" in general, when the change is one of magnitude only, as for instance, "per cent rate of (compound) interest," "per cent rate of discharge" of a reservoir or of a condenser, "per cent rate of decay" of a radioactive substance, etc. A "per cent rate" is called "angular velocity" in mathematical language.

6. If the quantity under consideration has direction as well as magnitude, it can change its value without changing its magnitude, that is, it can rotate. The change is then called "angular" in ordinary language as well as in mathematics and is specified in a number of ways, such as revolutions, or right angles, or degrees, or "radians" the latter term meaning the length of the arc (along which the rotation takes place) in per cent of the length of the rotating line, very similar to the per cent change in magnitude, but unfortunately this method of measuring circular angles is not commonly appreciated although it is a very natural method, if not the only natural method.

7. The angle which the rotating quantity tends to produce per unit of time is called its "angular velocity" and is ordinarily measured in revolutions per minute, although a more natural way (in fact, in a sense, the only natural way) to measure or specify it would have been in "per cent radius" *e. g.* (that is, radians, for, radian means per cent radius) per unit of time. For instance, to say that the angular velocity is five radians per second means that a point at the end of any assumed radius covers a distance equal to five radii in one second. In other words, the natural way of specifying an angular velocity is to specify the tangential velocity as a percentage of the length of the radius. Although the popular mind has grasped the fundamental concept of percentages in linear changes, unfortunately it has not grasped the idea of percentages in quadrature or rotary changes.

8. In speaking of arcs as subtending angles, the angles are not subtended at the origin or at any other point, but at the radius vector. Hence is the necessity for dividing the arc by the radius vector to obtain the angle.

9. When the radius vector is varying in magnitude, the angle of an arc is obtained by the summation

$$\int_{R_1}^{R_2} \frac{dR}{R} = L n R_2/R_1$$

Let the two limits of integration be 20 and 30 respectively.

$$\begin{aligned} L n (1.5) &= 2.3 \times \text{Log} (1.5) \\ &= 2.3 \times 0.176 \\ &= 0.405 \text{ hyperbolic} \\ &\quad \text{radians.} \end{aligned}$$

8. In speaking of change (of either kind) as a per cent change, the percentage is based on the value of the quantity in which the change is taking place. This point so clear in ordinary language is not so clear in mathematical definitions.
9. When the quantity is varying in magnitude, the change must be expressed not in per cent of the initial value of the quantity, nor of the final but of a mean equivalent value. When only a very small change is considered, the mean value of the quantity is sufficiently approximated by either the initial or the final value or the arithmetic mean of the two. For considerable changes an arithmetic mean value of R will not do, but the percentage may then be calculated in a number of steps as in compound interest. For instance, if the quantity changes from 20 to 30, the percentage of the first unit gain is $1/20.5$, the second $1/21.5$, the third $1/22.5$, etc. and the sum of ten such terms gives the total percentage gain (approximately) which in this case adds up to 0.405, (what is called forty and a half per cent) and happens to check the correct answer in this case to the third significant figure.

THE RADIUS VECTOR

When the radius vector is given, the angle θ between itself and the unit radius vector R_1 of zero angle is,

$$\theta = L n R - L n R_1 = L n R/R_1 \quad (12)$$

Fig. 7

Fig. 8

$$\text{Hence } R = R_1 e^{\theta} \quad (13)$$

This last result gives a physical interpretation to the exponential function as follows. If a quantity, with any initial value R_0 , changes (θ) radians, *i. e.*, (θ) per cent (compound percentage), its value becomes,

$$R_{\theta} = R_0 e^{\theta} \quad (14)$$

The percentage (θ) , however, may have any complex value. It may be a "real" number, so called, in which case the quantity has varied in magnitude only; or it may be a quadrature number, in which case the quantity has varied at right angles to itself, that is, rotated; or again, it may be a complex number, in which case the quantity has both rotated and changed in length. In the foregoing, (θ) is taken as the total complex angle.

If the quantity is varying continuously, it traces a path or curve. Assuming the velocity constant, if it is "real," that is, like itself or in-phase, as in

$$R = R_1 e^{w t} \quad (15)$$

the path is a straight line (Fig. 7). If the angular

velocity is imaginary, that is, quadrature, as in

$$R = R_1 e^{j\omega_2 t} \quad (16)$$

the path is a circle (Fig. 8); and, if the angular velocity is general or complex, with in phase and quadrature components as in

$$R = R_1 e^{(w_1 + jw_2)t} \quad (17)$$

the path is an exponential spiral⁴ (Fig. 9). The circle applies to undamped harmonic waves; the straight line, with exponential scale, (usually plotted to rectangular coordinates as increasing or decreasing exponential), applies in general to the uniformly damped d-c. or non-periodic quantities; and, the exponential spiral applies to uniformly damped harmonic quantities like the oscillatory discharge of a condenser, etc. The increasing exponential spiral and the decreasing exponential spiral are the images of each other as from a mirror, or an increasing exponential spiral may be considered as decreasing by reversing the direction of rotation, and vice versa.

The exponential spiral of Fig. 9 is of particular interest, for it gives the value of the radius vector both in magnitude and phase angle for any given complex angle. This is the only direct physical representation of the radius vector as it traces a complex angle. In fact, we might speak of it as the *photograph* of the radius vector as it traces a complex angle, in contrast with other graphical constructions which may in some sense be considered as a *representation*. The frame of the exponential spiral deserves special consideration, for it forms the basis of the physical interpretation as outlined in this paper and will be made use of in obtaining the sines and cosines of complex angles. This framework is shown in Fig. 10 as two systems of mutu-

Fig. 9

ally perpendicular lines; a system of radial lines and a system of circular lines, with common center or origin. The radial lines are graduated logarithmically and measure the hyperbolic angles in radians; the circular lines are graduated uniformly and measure the circular or quadrature angles in radians. The two sets of angles are at right angles to each other as they ought to be. Given the circular and hyperbolic components of a complex angle, the corresponding point is at once

4. Ordinarily called a "logarithmic spiral." Exponential and logarithmic functions are merely the inverse of each other.

located. The vector from the origin to this point gives the radius vector in magnitude and phase angle. The magnitude of the radius vector is measured linearly to some scale. Example: find the radii vector R_1 and R_2 which have the angles $+(0.5 + j\pi/6)$ and $-(0.5 + j\pi/6)$ respectively (Fig. 10). It will be observed that the hyperbolic angle determines only the magnitude, the circular angle the direction of the radius vector. Thus,

$$R_1 = e^{+0.5} (\cos \pi/6 + j \sin \pi/6) \quad (18)$$

$$R_2 = e^{-0.5} (\cos \pi/6 - j \sin \pi/6) \quad (19)$$

Fig. 10

LOGARITHMS OF NEGATIVE NUMBERS

In the expression for the radius vector R , having an initial value R_1 of plus unity with zero angle,

$$R = R_1 e^{\theta} \quad (20a)$$

$$\text{or} \quad R/R_1 = e^{\theta} \quad (21b)$$

if we assume (θ) as equal to (πj) , the radius vector rotates through π circular radians, that is, 180 deg. and becomes minus unity, and we have,

$$R/R_1 = e^{\pi j} = -1 \quad (21)$$

But in the general expression,

$$R/R_1 = e^{\theta} \quad (22)$$

(θ) is the logarithm of (R/R_1) and, therefore, from

$$R/R_1 = e^{\pi j} = -1 \quad (23)$$

we must conclude that (πj) is the logarithm of (-1) . This solves the problem of what the logarithm of a negative number could be. Thus,

$$L n (-x) = L n (-1) (x) \quad (24)$$

$$= L n (-1) + L n (x) \quad (25)$$

$$= \pi j + L n (x) \quad (26)$$

Physically, it means this:

In the discussion of hyperbolic angles especially in connection with Fig. 5, it was seen that "angle," "percentage" and "logarithm" were synonymous terms. Since, as it has already been shown that "angle" and "percentage" are synonymous terms for circular angles as well as for hyperbolic angles, therefore, we may

extend our idea of a "logarithm" and identify it with "circular" angles as well as with "hyperbolic" angles. The foregoing mathematical transformation can then be obtained by an extremely simple physical reasoning. Thus, considering $(+1)$ as a unit radius vector at zero angle.

$$(1) \text{ What is the angle of } (+1) \quad ? \quad 0 \quad (27a)$$

$$\text{ " " " logarithm of } (+1) \quad ? \quad 0 \quad (27b)$$

$$(2) \text{ What is the angle of } (+j)^5 \quad ? \quad j\pi/2 \quad (28a)$$

$$\text{ " " " logarithm of } (+j) \quad ? \quad j\pi/2 \quad (28b)$$

$$(3) \text{ What is the angle of } (-1) \quad ? \quad \pi j \quad (29a)$$

$$\text{ " " " logarithm of } (-1) \quad ? \quad \pi j \quad (29b)$$

$$(4) \text{ What is the angle of } (-j)^6 \quad ? \quad 3\pi j/2 \quad (30a)$$

$$\text{ " " " logarithm of } (-j) \quad ? \quad 3\pi j/2 \quad (30b)$$

$$(5) \text{ What is the angle of } (+1)^7 \quad ? \quad 2\pi j \quad (31a)$$

$$\text{ " " " logarithm of } (+1) \quad ? \quad 2\pi j \quad (31b)$$

These examples not only illustrate the case of the logarithms of (j) besides that of (-1) but, comparing item No. 1 with No. 5, it is seen that a logarithm is periodic with a quadrature periodicity. That is, adding or subtracting $2\pi j$ or an integral multiple of it to a logarithm leaves its value unaffected. This, however, need not startle us, for any kind of quantity is periodic for that matter; that is, rotation through 2π circular angles brings a quantity back to its original value. This, then, is the physical meaning of the imaginary, that is quadrature or circular, periodicity of hyperbolic functions, a characteristic true not exclusively of hyperbolic functions but of circular functions and of every other function as well. The reason why this appears like a mathematical mystery to many is simply due to an incorrect trigonometric nomenclature by which, instead of making a distinction between real (that is, linear or in-phase) and circular (or quadrature) angles, calling linear angles (θ) , and circular angles $(j\theta)$, and having only one kind of sine and one kind of cosine, we have two kinds of angles and two kinds of trigonometric functions. It is probably not too much to think that the early workers who established these nomenclatures had only a hazy conception of these physical relationships. Ordinarily, a circular angle is written as (θ) instead of $(j\theta)$, and the periodicity of the trigonometric functions is given by an equation like

$$\cos(\theta) = \cos(\theta + 2\pi n) \quad (32)$$

which if written as

$$\cosh(j\theta) = \cosh(j\theta + 2\pi nj) \quad (33)$$

$$\text{exactly as } \cosh(\phi) = \cosh(\phi + 2\pi nj), \quad (34)$$

shows that the periodicity of circular angles is also imaginary that is, quadrature, because equation (33)

5. j must not be ignored, so that the circular, that is, quadrature, angle may not be confused with the hyperbolic angle.

6. Meaning 270 deg.

7. Meaning 360 deg.

is identically the same thing as equation (32) except that it is in hyperbolic garb.

PHYSICAL MEANING OF SINE AND COSINE

Let (θ) be a complex angle, and let the value of the radius vector for $(+\theta)$ be R_1 , and for $(-\theta)$ be R_2 . The vector mean value of R_1 and R_2 is called the cosine of angle (θ) : hyperbolic cosine, if (θ) is a real or in-phase angle; circular cosine, if (θ) is a quadrature angle.

The value of the radius vector for $(+\theta)$ is $e^{+\theta}$, and for $(-\theta)$ it is $e^{-\theta}$, and the mean value of the two gives the cosine, as

$$\cosh(\theta) = \frac{R_1 + R_2}{2} = \frac{e^{+\theta} + e^{-\theta}}{2} \quad (35)$$

We prefer to write "cosh," instead of "cos," because we are treating the hyperbolic angle as real or linear, and the circular angle as quadrature, as this view is much more natural.

The foregoing formula agrees with the usual geometric representation of the cosine of a circular angle as the projection of the radius vector on the $X =$ axis as shown in Fig. 11.⁸

Fig. 11

For circular angles the numerical value and projection of the radius vector is the same for $(-\theta)$ as for $(+\theta)$, and therefore the definition of the cosine could be given either way, as mean sum or as projection, but not so with the hyperbolic functions. Assuming (θ) as an in-phase angle, $e^{+\theta}$ and $e^{-\theta}$ are not equal in magnitude neither are their projections, for their projections are identical with themselves. We could, therefore, define a cosine, if we pleased, either as the mean projection or as the (vectorial) mean value of the radius vector for $(+\theta)$ and $(-\theta)$. The cosine then may be looked upon as a vector parallel to the mean radius vector, as is clear from Figs. 11 and 12.

Turning to the sine of (θ) , it is the mean (vector)

8. This vectorial point of view is the physical basis of the treatment of a harmonic flux as the resultant of two constant fluxes rotating in opposite directions in single-phase induction motors, as will be better evident in section on "Characteristics of Sines."

difference of the radius vector for $(+\theta)$ and $(-\theta)$.

Thus,

$$\sinh(\theta) = \frac{R_1 - R_2}{2} = \frac{e^{+\theta} - e^{-\theta}}{2} \quad (36)$$

If (θ) is a real angle, the sine is hyperbolic, if a quadrature angle, the sine is circular.

The idea of projection does not hold very well for the sine of both trigonometric and hyperbolic angles without undue straining, but the idea of "one half vector sum" for cosine, and "one half vector difference" for sine, holds equally for circular as well as for hyperbolic angles.

For a hyperbolic angle, the sine is a vector in phase with the radius vector; but for a circular angle, the sine is perpendicular to the mean radius vector as will

Fig. 12

be seen from Figs. 11 and 12. From this it follows that, if θ is an in-phase or hyperbolic angle,

$$\sinh(j\theta) = j \sin(\theta) \quad (37)$$

$$\text{whereas} \quad \cosh(j\theta) = \cos(\theta) \quad (38)$$

Other trigonometric functions need not be considered here, because they can all be expressed in terms of sines and cosines.

GRAPHICAL CONSTRUCTION

Graphical constructions for the sines and cosines of complex angles follow at once from their definitions as the mean sum or mean difference of the radius vector for the plus and minus angle, and from the graphical construction for the radius vector of a complex angle. The framework of Fig. 10 is used for this purpose. Given the complex angle $(\theta_1 + j\theta_2)$; the radius vector R_1 for plus $(\theta_1 + j\theta_2)$, and the radius vector R_2 for minus $(\theta_1 + j\theta_2)$ are located. Then, half their vector sum and difference give the trigonometric functions:

$$\cosh(\theta_1 + j\theta_2) = \frac{R_1 + R_2}{2} \quad (39)$$

$$\sinh(\theta_1 + j\theta_2) = \frac{R_1 - R_2}{2} \quad (40)$$

The addition and subtraction of R_1 and R_2 are carried out vectorially as shown in Fig. 10. Calculated analytically, we have

$$\begin{aligned} \cosh(\theta_1 + j\theta_2) &= \frac{e^{+\theta_1}}{2} (\cos \theta_2 + j \sin \theta_2) \\ &\quad + \frac{e^{-\theta_1}}{2} (\cos \theta_2 - j \sin \theta_2) \end{aligned} \quad (41)$$

$$\begin{aligned} \sinh(\theta_1 + j\theta_2) &= \frac{e^{+\theta_1}}{2} (\cos \theta_2 + j \sin \theta_2) \\ &\quad + \frac{e^{-\theta_1}}{2} (\cos \theta_2 - j \sin \theta_2) \end{aligned} \quad (42)$$

CHARACTERISTICS OF SINES AND COSINES

The graphical constructions for the trigonometric functions give a true physical picture but can not naturally fully convey the various characteristics of these functions at sight. The solution of many physical problems involves differential equations, that is, requires a knowledge of the "rate of change" characteristics of functions. We may therefore analyze such characteristics of the radius vector as it traces circular or hyperbolic or complex angles to see how and why sines and cosines of these angles come in.

If a quantity is varying at a constant percentage, its absolute rate of change is proportional to itself. If the function is increasing, its rate of change, that is, its velocity, is positive; if decreasing, its velocity is negative; if rotating without change of length, its velocity is j , that is, quadrature; and, if both rotating and changing in length, its velocity is general or complex. If the rate of change or velocity is proportional to the quantity, the rate of change of the rate of change, that is, the rate of change of the velocity, or, in other words, the acceleration, is also proportional to the quantity. If the velocity is in-phase, the acceleration is also in-phase and has the same direction as the original quantity, regardless of whether the quantity is increasing or decreasing. If the velocity is in quadrature, the acceleration is in quadrature with the velocity and thus negative with respect to the original quantity. Thus, if a quantity is rotating, (*i. e.*, varying at a constant quadrature percentage of itself at every point), its acceleration is proportional to itself but negative, regardless of whether it is rotating positively or negatively, that is, clockwise or counter-clockwise. If then, we know by any physical consideration that the acceleration of a quantity R is proportional to itself and has the same sign as itself, it must be either a positively rotating quantity (equation 43); or a negatively rotating quantity (equation 44); or the resultant of two quantities rotating in opposite directions (equations 45 and 46), that is, a harmonic quantity. Conversely, a harmonic quantity may be considered as the resultant of two constant vector components rotating in opposite directions as is assumed in the theory of the single-phase induction motor.

$$R = A e^{+j\omega t} \quad (43)$$

$$\text{or} \quad = A e^{-j\omega t} \quad (44)$$

$$\text{or} \quad = A (e^{+j\omega t} + e^{-j\omega t}) = 2A \cos(\omega t) \quad (45)$$

$$\text{or} \quad = A (e^{+j\omega t} - e^{-j\omega t}) = 2A \sin(\omega t) \quad (46)$$

From this it follows that the sine and the cosine functions are more general than the simple exponential functions, and include the common characteristics of both the increasing and the decreasing exponentials. This applies to the hyperbolic functions as well as to the circular. Thus, if the acceleration of the quantity

R is proportional to itself and in the same direction, then, the equation of the quantity is of the form.

$$R = A e^{wt} \quad (47)$$

$$\text{or} \quad = A e^{-wt} \quad (48)$$

$$\text{or} \quad = A (e^{wt} + e^{-wt}) = 2 A \cosh (w t) \quad (49)$$

$$\text{or} \quad = A (e^{wt} - e^{-wt}) = 2 A \sinh (w t) \quad (50)$$

Thus, again, the sine and cosine functions are more general than the simple exponential, and include the acceleration characteristics of both the increasing and the decreasing exponential.

Just as the trigonometric functions can be compounded from the simple exponentials, so, the simple exponentials can be given in terms of the trigonometric functions. Thus,

$$e^{\pm wt} = \cosh (w t) \pm \sinh (w t) \quad (51)$$

$$e^{\pm j w t} = \cos (w t) \pm j \sin (w t) \quad (52)$$

In these equations, the exponential form is of course to be preferred to the trigonometric form on account of its simplicity.

The application of the characteristics of sines and cosines may be illustrated by a few familiar examples:

An object is displaced against an elastic force which varies directly with the displacement but is directed opposite to it. If the body is released, the force accelerates it and since the force and therefore the acceleration are proportional to the displacement but opposite to it, the motion will be like a circular sine or cosine function, that is, harmonic.

A condenser is discharged through an inductance. The rate of change of the current produces voltage across the inductance equal and opposite to that of the condenser. That is, the condenser voltage is proportional and opposite to the rate of change of the current. However, a condenser current is proportional to the rate of change of the condenser voltage, and since the condenser voltage is proportional (but negative) to the rate of change of the current, the rate of change of the condenser voltage and, hence, the current are proportional to the acceleration of the current. Thus, the current and its acceleration are proportional to each other and opposed, and therefore the current is a circular sine or cosine function, that is, harmonic.

A leaky transmission line is carrying current. Assume it direct current for simplicity. As we advance along the line the current will become less and less, due to leakage to ground. The rate at which the line current is changing is equal to the leakage current, and this rate is negative because the current is decreasing. The rate at which the leakage current changes along the line is proportional to the line current and is negative with respect to it in its turn because the leakage current also decreases. Thus the line current and its second rate of change are proportional to each other and have the same sign, and therefore, the distribution

of current along the line must be like a hyperbolic sine or cosine.

Analytically,

$$\text{If} \quad \frac{d^2 y}{d t^2} = + w^2 y, \text{ then,}$$

$$y = A \sinh (w t), \text{ or,} \\ = B \cosh (w t), \text{ or their combination}$$

$$\text{If} \quad \frac{d^2 y}{d t^2} = - w^2 y, \text{ then,}$$

$$y = A \sin (w t), \text{ or,} \\ = B \cos (w t), \text{ or their combination}$$

$$\text{And, if,} \quad \frac{d^2 y}{d t^2} = (w_1 + j w_2)^2 y, \text{ then,}$$

$$y = A \sinh (w_1 + j w_2) t, \text{ or} \\ = B \cosh (w_1 + j w_2) t, \text{ or} \\ = C \sin (j w_1 - w_2) t, \text{ or} \\ = D \cos (j w_1 - w_2) t.$$

These solutions are of course the simpler solutions, and still more general solutions are obtained by combining the simpler solutions, but that is another subject.

COMPLEX ANGLES IN SPACE

All the foregoing discussions were limited to a plane and one little difficulty was encountered in having the quadrature component of a vector angle a curve instead of a straight line, which was partially excused on the ground that if the arc was taken short enough it would be straight. The reason why the arc as a vector could not be represented by its chord was stated to be due to the fact that any finite chord could not be perpendicular to the radius vector at every point along that chord. In other words, the arc was curved with respect to the X -axis but straight with respect to the rotating radius vector, having a constant angle with respect to it at every position, for what is the fundamental definition of a straight line (in terms of differential equations) if not this, that its slope (therefore angle) is constant? The argument is admittedly a trifle strained; the reason is that it is limited to a plane. However, if we take a three-dimensional view of the matter, these arguments become unnecessary, for we then find that the quadrature angle is really to be represented by the axis of the arc. It then is easy to see that no matter how curved the arc, its axis will be straight. In plane analysis, however, there is no room for an axis, the third dimension being barred, and therefore the arc itself is taken to represent the angle. Representing the quadrature (circular) angle by the axis of the arc does not alter the fact that the circular and hyperbolic angle will be at right angles with each other, because hyperbolic angle will still be represented by the component of the path parallel to the radius vector, and, therefore, the axis of the quadrature component perpendicular to the plane of the path will

also be perpendicular to the in-phase component of the path.

In treatises on vector analysis it is shown that the product, or quotient, of two vectors in quadrature is another vector and is perpendicular to the plane of the two factors. Referring now to Fig. 3, the elementary circular angle is

$$d\theta_2 = \frac{dR_2}{R}$$

which is the quotient of two vectors in quadrature, and is therefore, a vector perpendicular to the plane of (dR_2) and R . Of course, it is difficult to show this normal in a flat diagram and therefore it is rotated into the plane of the diagram to make it visible, in which case it coincides with the circular arc, not with its chord. That is, when dR_2/R is represented by (dR_2), it is equivalent to rotating the normal through 90 deg. around the radius vector as axis into the plane of (dR_2) and (R) in infinitesimal steps.

Considering now the elementary hyperbolic angle,

$$d\theta_1 = \frac{dR_1}{R}$$

Fig. 3.

This is the quotient of two parallel vectors, and is therefore a scalar. In order that the representation may be consistent and show the true relationship between the two kinds of angles, if the circular angle is multiplied by (R) so must the hyperbolic angle be multiplied by R . The result is that this multiplication by R rotates the vector circular angle into the plane of the diagram and identifies it with the circular arc dR_2 , and changes the scalar hyperbolic angle into vector and identifies it with the radial vector component dR_1 of the path in-phase with the radius vector. Looking at this from another point of view, if we are interested in showing the relationship of circular and hyperbolic angles, then,

$$\frac{dR_1}{R} : \frac{dR_2}{R} = dR_1 : dR_2$$

Hence, the representation of the circular and hyperbolic angles by the vectors dR_2 and dR_1 is justified.

It may be evident from the foregoing critical analysis that a complex angle is a vector in the same sense and limitation as an impedance; the per cent resistance component of an impedance corresponding to the hyperbolic angle, the per cent reactance component to the circular angle. In fact, the per cent vector impedance of a circuit is the complex angle of the circuit in radians. Strictly, of course, the percentage must be compound percentage not simple percentage. However, in small percentages, the distinction is negligible. When the percentages are large, or when the circuit has distributed constants the distinction can not be ignored.

If the radius vector traces a three dimensional curve, the quadrature component of the path may be in any one of an infinite number of planes and its determina-

tion requires two mutually perpendicular vectors in quadrature with the radius vector, of the form,

$$\theta = \theta_0 + j_1 \theta_1 + j_2 \theta_2$$

where j_1 and j_2 are the two reference vectors. As electrical problems are as a rule in one plane, and those which are three-dimensional have such symmetry that they can be treated as problems in one plane, the three dimensional complex angle has little application for the engineer. However, it has been mentioned above to indicate that the physical interpretation developed in this paper covers even this more generalized angle, and for the guidance of those who may wish to make a more extended study of the subject.

Discussion

A. E. Kennelly: I think we are all indebted to Mr. Boyajian for bringing to our notice that we shall have to modify our views concerning angles, and their treatment by engineers.

I think that has been evident to a great number of us, but Mr. Boyajian has been the first to say so definitely. He has shown us how complex angles may be worked. I think that the method he gives is workable and reliable, but I would like to make one reservation in regard to the treatment that he offers.

I think we all agree in regard to what he says about circular angles, and that a hyperbolic angle is an imaginary circular angle, also that a circular angle is an imaginary hyperbolic angle; but he takes the position, if I understood him correctly, that for a hyperbolic angle, it is not necessary to involve any kind of rotation, that it is simply a one-dimensional movement, or a one-dimensional quantity.

I think that while for ordinary purposes that may be true, and that processes of calculation may be conducted on that basis, but to say that the hyperbolic angle is of one-dimensional quantity, is I believe, limiting it unnecessarily. It seems to me that we can use Mr. Boyajian's method without necessarily confining ourselves to that point of the doctrine. I still think that we can maintain the idea of rotation through an area in connection with a hyperbolic angle, and one reason for that is presented in these slides of a model for projecting the cosines and sines of a complex hyperbolic angle, and which attributes rotation of a radius vector to both the hyperbolic and circular components of the complex angle.

A. Boyajian: As for the reservation which Dr. Kennelly wishes to make so as to maintain the idea of rotation in connection with hyperbolic angles, may I submit the following considerations:

When the radius vector traces a hyperbolic sector, it certainly also traces a circular angle by virtue of its rotation. According to usual schemes, the area of this hyperbolic sector is made use of to represent the numerical value of the hyperbolic angle, and the circular angle which the radius vector has traced is ignored. As I have stated in my paper this is permissible representation but is not completely illustrative of the essence of a hyperbolic angle. If we were called upon to make a representation of a hyperbolic angle, in which there shall be no trace of a circular angle, I think we shall have to fall back on the straight line diagram given in my paper in accordance with the newer point of view.

Dr. Kennelly feels that to make the hyperbolic angle a one-dimensional quantity, that is, to eliminate rotation from the representation of hyperbolic angles, limits them unnecessarily. I feel however that the idea of rotation which has been forced on hyperbolic angles in the past has unnecessarily handicapped the interpretation of the true physical nature of hyperbolic angles. The new point of view, by eliminating this unnecessary condition of rotation, gives greater freedom to the hyperbolic angles and to their interpretation.

the steady state conditions of an electrical system, *e. g.* by connecting or disconnecting a load, or by producing or interrupting a short circuit, the new steady state conditions are generally reached after a very short time, during which so-called "transient phenomena" or "transients" take place. As the flow of effective and reactive power are not the same in the different parts of the system during the first and the second steady state, the necessary adjustment is made by transient electromagnetic "traveling waves," *i. e.* waves of both voltage and current, carrying energy from one part of the system to another.

The values of voltage and current in these waves, or as we shall say the amplitude of the waves, may reach abnormally high values and become destructive to the line. The steepness of the front of the wave also, *i. e.*, the high rate of change of the voltage and current with the time may be harmful. Therefore, a knowledge of the "attenuation" or diminution of amplitude of the wave with the time, and of the "distortion" or change in the wave shape, is of engineering importance. Our present knowledge of the subject is still far from being complete. Joulian and dielectric losses produce both attenuation and distortion, but there may be other causes. C. P. Steinmetz¹ considered the possible influence of radiation, but his results may be questioned.

From this began the present investigation, aiming towards the determination of the radiation effect upon the decay of traveling waves along transmission lines. It was found that the radiation effect is entirely negligible compared with the effect of joulian dissipation, and hence that, from an engineering point of view radiation can be ignored in connection with transmission lines.

CLASSICAL THEORY OF THE PROPAGATION OF WAVES ALONG ELECTRIC LINES

The classical theory of the propagation of waves along a line, *i. e.*, a system of straight parallel outgoing and return conductors, rests upon two assumptions: the displacement currents in the dielectric, parallel to the conductors are negligible, and the so-called "four distributed constants" of the line can be determined. They are the resistance, inductance, leakance and capacity per unit length of the line (R, L, G, C). These quantities are functions of the frequency for sinusoidal steady alternating current; for transient currents, they are somewhat indeterminate, and an average value must be assumed.

The fundamental equation for the propagation of the voltage V or the current I is under these assumptions

$$LC \frac{\partial^2 V}{\partial t^2} + (RC + LG) \frac{\partial V}{\partial t} + RGV = \frac{\partial^2 V}{\partial x^2} \quad (1)$$

where t denotes the time and x the space coordinate along the line. From this equation, well known conclusions can be drawn, of which the following only need be considered here:

1. An electric disturbance, *i. e.*, a discontinuity of voltage or current, is always propagated along any line at the constant speed $v = 1 : \sqrt{LC}$, whether there is resistance and leakance or not.

2. The disturbance is attenuated exponentially with the time according to

$$\exp [-1/2 (R/L + G/C) t].$$

3. The distortion of the disturbance depends on the value of the term

$$1/2 (R/L - G/C)$$

In the case of transmission lines, the attenuation is the controlling factor, and the wave has died out before any appreciable distortion has taken place. Thus a steep wave front will very nearly keep its shape during the propagation.

This conclusion, however, is based on the two assumptions made; the first amounts to saying that the variations of V and I along the line will not be too rapid, and the second, that the penetration of the current in the wires is instantaneous, neither of which is true at the very front of the wave. From Maxwell's point of view, the classical theory amounts to a plane wave theory, *i. e.*, the electromagnetic field around the wires lies in planes; this implies that the dissipation is taking place everywhere in the plane wave, instead of being localized in the wires. This has been shown very clearly by O. Heaviside in his "Electrical Papers."

We thus consider the question of change in the wave shape near the front of the wave, due to the resistance of the line, still as an open question.

DR. STEINMETZ'S THEORY OF THE RADIATION

Dr. Steinmetz's theory of the radiation from transmission lines deals only with the electromagnetic field. The electric and the magnetic fields are supposed to propagate from the wires perpendicularly into space, thus implying a flow of energy from the wires into space, and also non-transversal electromagnetic waves, two conceptions in conflict with Maxwell's theory. It is shown², as an immediate deduction of Maxwell's equations that plane electromagnetic transversal waves are propagated undistorted and unattenuated, at the speed of light in the surrounding medium, along a pair of infinitely long straight perfect conductors, *i. e.*, along a line without joulian or leakage losses; thus there is no radiation. Non-perfect conductors, as it has been shown, introduce more complexity, because the waves are no more plane waves, but nothing is changed from the radiation point of view.³ The flow of energy in the dielectric is evidently parallel to the wires, with a small component directed

(Pierce, *El. waves*, Chapter IX. F. Cutting, *Proc. I. R. E.*, p. 129, 1922). In the case of a straight oscillator, Abraham found the present method in quantitative agreement with the more elaborate solution based on the full solution of Maxwell's equation. (*Phys. Zeit.*, 2, p. 329, 1901). It is to be noticed that in the case of antennas, the radiation is the controlling factor and the joulian dissipation only secondary, while in the case of transmission lines the conditions are reversed. This strengthens our conclusions even more.

We first consider perfect conductors, and later take into account the influence of joulian losses.

When any kind of disturbance of current is propagated along a perfect thin wire, Heaviside shows how the corresponding electromagnetic field is set up by means of spherical traveling waves. (*El. Theory*, Vol. I, art. 54, etc., where what he calls the "motion of a charge" is entirely equivalent to the propagation of a "current along a wire.") The reflection of current and the corresponding electromagnetic field generated by spherical waves originating at the point of reflection are indicated. (in *El. Theory*, Vol. II, art. 393, 394.) This theory neglects the diameter of the wires, compared to the length of the disturbance. At that order of approximation, the current (or traveling wave) is propagated undistorted and unattenuated at the speed of light in the air, and reflected as usual, even with regard to possible radiation.

We thus take the distribution of current along the line, either a stationary or traveling sinusoidal one in the steady a-c. case, or a traveling rectangular one in the case of a sudden impulse.

STATIONARY RADIATION FROM A TRANSMISSION LINE

We mean the radiation that takes place under steady a-c. conditions by means of stationary waves, such as the natural oscillations of a line, without joulian losses.

Different modes exist, according to the terminal conditions to which the line is subjected. We consider, as an example, a line free at both ends, thus capable of half-wave length oscillations and multiples thereof.

We assume spherical polar coordinates, with the origin O_1 at the middle of the length l of the wire No. 1, and the polar axis $+z$ along the same wire.

A length along the wires will be z , r_0 is the distance between a point P and the origin O_1 , θ_0 is the angle between O_1P and the $+z$ axis; r and θ are the same quantities referred to any point of the wires instead of to O_1 ; ϕ is the angle (longitude) that the plane PO_1z makes with the plane of the wires, measured from the direction opposite to the second wire No. 2; d is the distance between the wires. (Fig. 1.)

The distribution of the current along wire 1 is from the preceding:

$$I = i \cos \frac{\pi n z}{l} \sin \frac{\pi n}{l} c t \quad (3)$$

with $-l/2 \leq z \leq +l/2$, and with reversed sign for the current along wire 2. I is positive, if directed along $+z$; n is an odd integer giving the "order" of the os-

cillation; c represents the velocity of light; i is the maximum current.

We have for the electromagnetic field due to the rate of change of a current element $I dz$, at distances large compared to the wave length of the oscillation, the values first given by Hertz under an equivalent form (*Wied. Ann.* 36, p. 1, 1889; or *Ausbr. Elekt. Kraft.*, p. 153, 1892).

$$E = H = 1/c \frac{\sin \theta}{r} \frac{d}{dt} (\hat{I} dz) \quad (4)$$

where $I dz$ is the same as the time derivative of the moment of Hertz's doublet. $\hat{I}$ means I , where the time t has been replaced by $t - r/c$; the current I and magnetic force H are expressed in electromagnetic units; the electric force E is expressed in electrostatic units. At a point P , E lies in the plane of P and the

FIG. 1

wire, and is perpendicular to r ; at the same point, H is perpendicular to this plane. The positive directions are shown on the diagram. We consider the whole transmission line as a large sum of such current elements. At the point P , the elementary H' 's add themselves, but all the E' 's do not fall in the same direction. They will do so, however, and will add, provided we recede far enough from the line, because all differences in direction then vanish, i. e. θ can be taken as a constant. We can write neglecting quantities of the second order, i. e., $1/r^2$ as compared to $1/r$:

$$E = H = 1/c \frac{\sin \theta_0}{r_0} \frac{a}{dt} \int_{-l/2}^{+l/2} (\hat{I}_1 - \hat{I}_2) dz \quad (5)$$

where I_1 and I_2 , the currents in the wires 1 and 2 are to be given their proper time phase $t - r/c$.

At great distances, we have with the same approximation

$$\begin{aligned} \text{for wire 1 } r &= r_0 - z \cos \theta_0 \\ \text{for wire 2 } r &= r_0 - z \cos \theta_0 + d \sin \theta_0 \cos \phi_0 \end{aligned} \quad (6)$$

Still with the same approximation, and neglecting

the higher powers of d/l , which is of the order of 10^{-3} to 10^{-5} , (3) gives

$$\begin{aligned} \hat{I}_1 - \hat{I}_2 = i \cdot \cos \frac{\pi n z}{l} \cdot \cos \frac{\pi n}{l} (c t - r_0 \\ + z \cos \theta_0) \cdot \frac{\pi n d}{l} \sin \theta_0 \cos \phi_0 \end{aligned} \quad (7)$$

In this expression, z cannot be neglected as compared with r_0 , because these quantities figure as argument of the function $\cos$. Substituting in (5), performing the time⁴ derivation and the integration with respect to z , we get

$$\begin{aligned} E = H = (-1)^{\frac{n+1}{2}} 2i \cdot \frac{\pi n d}{l} \\ \frac{\sin \frac{\pi n}{l} (c t - r_0)}{r_0} \cos \left(\frac{\pi n}{2} \cos \theta_0 \right) \cos \phi_0 \end{aligned} \quad (8)$$

where n is an odd positive integer, and the signs agree with the assumed convention. This formula represents the steady electromagnetic field from an a-c.

FIG. 2

transmission line of length l , at a distance r_0 from the origin so large that the ratio l/r_0 is very small. The electric and magnetic forces E and H lie on pure spherical waves, traveling at the speed c from the origin on the line. We consider the intersection of the $+z$ axis with a sphere as a positive pole (origin of the angles θ) of the sphere. Then, the electric force is directed along meridians and the magnetic force along parallels; the sign in formula (8) is in accordance with the original conventions. (Fig. 2).

The main difference between the "field of radiation" of a transmission line and that of a single wire line (antenna), is that, in the first case, the forces are only of the order of d/l , compared to the second case, which is very small.

4. See note 1.

It is seen that the electric and magnetic forces are perpendicular to the direction of propagation, (the radius of the sphere), as it must be in the case of pure transversal waves; and thus Poynting's vector $E \times H$ is perpendicular to the sphere. Hence, we have for the flow of energy or energy radiated per unit of time

$$S = \frac{c}{4\pi} \int E H d\Sigma \quad (9)$$

integrated over the area of the sphere of radius r_0 , with $d\Sigma$ as element of area.⁵

Substituting the values (8) for E and H , and performing the integrations, and taking the time average, we obtain:

$$S = C \cdot \pi^2/2 \left(\frac{n d}{l} \right)^2 \cdot i^2 \text{ ergs/sec.} \quad (10)$$

or

$$= 15 \cdot \pi^2 \left(\frac{n d}{l} \right)^2 I^2 = 15 \left(\frac{2\pi d}{\lambda} \right)^2 I^2 \text{ watts} \quad (11)$$

where I is here the maximum current in amperes and λ the wave length. The power radiated by an oscillating transmission line, open at both ends, is thus, for a given current, numerically proportional to the square of the ratio of the distance between the wires to the wave length of the oscillation.

We compare the power radiated to the power dissipated by heat, taking as an example the line whose constants are

No. 00 B & S

$d = 183 \text{ cm.}$

$l = 100 \text{ km.}$

Total d-c. resist. line = 48 ohms

Total external inductance = 0.238 henry

We have, for the power radiated S

for $n = 1$ $\lambda = 2 \times 10^7 \text{ cm.}$

$S = 0.5 \times 10^{-7} \text{ watts per max. ampere}$

$f = 1500 \text{ cycles/sec.}$

$n = 2001$ $\lambda \approx 10^4 \text{ cm.}$

$S = 0.2 \text{ watts per max. ampere}$

$f \approx 3 \times 10^6 \text{ cycles/sec.}$

Due to the sinusoidal distribution of current, the power dissipated by heat is only 48/4 watts per max. ampere at low frequency; it is about 60 times more at three million cycles.

Thus, even at three million cycles, the power radiated by the line is only 1/60 or 1.7 per cent of the power wasted in heat at low frequency, or 1/3600 of the total heat wasted at three million cycles. Hence, the radiation of oscillating transmission lines is entirely negligible in engineering practise.

Dr. Steinmetz's formulas amounted to writing the radiated power proportional to $d \cdot l/\lambda^2$ instead of d^2/λ^2 .

Similar results are obtained in the case of forced oscillations of a line or impressed a-c. and load to Carson's formula. (JOUR. A. I. E. E., Oct. 1921, p. 789.)

Instead of considering an ideal sinusoidal current

5. See Note 2.

distribution along the line, as when there are no losses, we might introduce the actual distribution given by the hyperbolic theory. There would be only more complication in the integrations, but the order of magnitude of the result would remain the same, *i. e.* proportional to d^2/λ^2 ; thus quite negligible.

TRANSIENT RADIATION FROM A TRANSMISSION LINE

We mean the radiation that accompanies the production of traveling waves. When a disturbance of current is suddenly produced at the end O of a semi-infinite, thin, perfectly conducting wire, it is propagated in first and very close approximation as seen above, unattenuated and undistorted, at the speed of light, along the wire. The wire is supposed to be the only conductor in the empty space. The accompanying electromagnetic field is propagated, at sufficient distance from the source, by spherical waves, also at the speed of light. Its expression at a point P is, when r is great, *i. e.*, such as to make $1/r^2$ negligible compared to $1/r$:

$$E = H = \hat{I}/r \cdot \frac{1 + \cos \theta}{\sin \theta} \quad (12)$$

r denotes the distance PO ; θ is the angle that PO makes with the wire; $\hat{I}$ the current at the origin O , given as a function of time t , where t has been replaced

by $t - \frac{r}{c}$: c is the speed of light. I and H are expressed in electromagnetic units; E is in electrostatic units. I is positive when flowing along the positive direction of the wire. The electric force E is directed along meridians; the magnetic force H along parallels.

This formula is substantiated⁶ by noticing that it verifies both Maxwell's equation for r large, and that for θ very small, it represents plane electromagnetic waves traveling at the speed c along an infinitely thin wire;

$$E = H = \frac{2\hat{I}}{l} \quad (13)$$

with $l = r \sin \theta$ being the distance of a near by point close to the wire. When the traveling disturbance of current reaches the end of the wire, it can be absorbed by the terminal apparatus without reflection; this is equivalent to starting at the end a new disturbance $-\hat{I}$, of opposite sign, but of same direction of propagation as the first, so that each cancels the other along the wire supposed to be extended. If there is partial or total reflection, a new superimposed disturbance of current $K\hat{I}$ is supposed to be sent along the wire from the end towards the origin, thus propagating in opposite direction, the value and sign of K , which is the coefficient of reflection, depend on the terminal conditions.

We shall consider, just for simplicity, as only disturbance of current the sudden starting or stopping of a constant current at the origin, *i. e.*, "rectangular

waves" of current. The stopping will be considered as the starting of a current of opposite sign, in the same direction of propagation.

The case of a *transmission line* reduces itself to the preceding case. We consider a line composed of two parallel semi-infinite wires originating in O_1 and O_2 and at the distance d apart. The coordinates used are the same as before, and are shown on the diagram, Fig. 3. A disturbance is produced at the origin, consisting of a suddenly flowing constant current $+I$ at O_1 and $-I$ at O_2 . At great distances from the source, the

FIG. 3

electromagnetic field of the disturbance will be given by the sum of two expressions like (12) where due regard is given to the position of the sources O_1 and O_2 and their

influence upon the "retardation" $t - \frac{r}{c}$, and also to

the sign of the disturbances. This supposes that the presence of one thin wire does not interfere with the electromagnetic field of the other wire at great dis-

6. See Note 3.

tances; the linearity of the electromagnetic equations permits the addition of the fields.

When a sufficient time has elapsed after the disturbance started at the origin, *i. e.*, when its spherical front will have reached a great distance, in the sense we gave to that expression, the electromagnetic field of the disturbance can be considered as composed of two parts. (See Fig. 3.) One, in the space common to both "front spheres" O_1 and O_2 , centered upon the sources O_1 and O_2 ; the other in the space between the two spherical surfaces, which can be considered as a very thin spherical shell of variable depth

$$d \sin \theta \cos \phi$$

this being equal to the distance $O_1 O_2$ projected in the direction considered (θ, ϕ). The electromagnetic field outside both spheres is obviously zero. In the shell, it is given by (12), with the proper sign for I , and lasts at a fixed point in the space during the time

$$|d/c \sin \theta \cos \phi|$$

the bars meaning an absolute value. Inside both spheres the electromagnetic field is vanishing, *i. e.*, of the order of $1/r^2$, except near the wires where it is very nearly a plane wave field. It is given there by the difference of two expressions like (13)

$$E = H = \frac{2I}{\rho_1} - \frac{2I}{\rho_2} \quad (14)$$

ρ_1 and ρ_2 being the distances of the point close to the wires. This is the well-known value of the electromagnetic field of a plane wave traveling along a perfect two-conductor line, as we considered it first from the classical point of view. Thus, besides the energy stored in the field of the traveling wave near the wires, there is also a small amount of energy present in the indefinitely expanding thin spherical shell of which we spoke, and which the classical theory does not account for. We consider this energy as the *transient radiation from a transmission line*, when acted upon by a sudden applied e. m. f. producing the current I in the line, because this energy is carried to infinity and thus is a net waste for the system. Its amount, calculated in a way entirely similar to that used in the case of the steady radiation above, is⁷

$$W = 3/2 d \cdot 10^{-9} \cdot I^2 \text{ joules} \quad (15)$$

where d is the distance between wires in cm. and I the sudden started constant current in amperes.

We consider as an example a *rectangular pulse* of current, *i. e.*, a traveling disturbance of constant current, extending over a length λ cm. The total waste by radiation will be twice as much as given by (15), because the same transient radiation occurs when suddenly stopping the current at the origin as when suddenly starting it. The total energy in Joules carried by the pulse along the wires, when it is far enough from

induction in henries per cm. of the line, I the current in amperes. For the line already considered, L is equal to 23.8×10^{-9} . Thus the ratio of the radiated energy to the energy contained in the plane electromagnetic field of the pulse is given by

$$\frac{3d}{23.8} 1/\lambda = .126 d/\lambda$$

or, for a pulse extending over a length λ one hundred times the distance d between the wires, only 0.1 per cent of the total energy of the pulse. It is to be noticed that the fundamental frequency of the pulse in this example is as high as 820,000 cycles. Taking as effective resistance the resistance at one million cycles (17.3 ohms per km. of line, Steinmetz loc. at p. 202), it is found that when the pulse travels only one third of its own length, it wastes in heat an amount of energy equal to the energy radiated. This shows how negligible is the effect of radiation.

When a rectangular wave of current reaches the end of a single wire, its stopping generates a new spherical

FIG. 4

wave, expanding at the velocity of light and centered upon the end R ; (Fig. 4) and which is tangent to the first spherical wave originating from O .

Similarly, in the case of a two wire line, a spherical shell of electric and magnetic field is generated, centered upon the two ends R_1 and R_2 , and tangent to the first shell originating from O_1 and O_2 . (Fig. 5.) Thus the total radiation will be the energy carried into infinite space by the two expanding spherical shells. As the two shells have the part $X_1 X_2$ partly in common, where their fields add to each other, the total energy radiated will not be exactly that obtained by adding the energies of both shells separately, but will be a little less. It is shown that taking this sum an error is committed that will not exceed the ratio of the angle

$\frac{X_1 X_2}{r}$ to 2, *i. e.*, of the order of d/l ,⁸ or between 10^{-3}

to 10^{-5} or less. Hence, to that approximation, we can say that *the starting current and successive reflections will each add a given amount to the energy lost by radiation*.

7. See note 4.

8. See note 6.

tion. The solution of specific cases is thus directly given by the preceding. We give the following results as illustrations of the method.

1. The *sudden* establishment from one end of a line of a sustained continuous current I , without reflection at the other end, wastes

$$3 d 10^{-9} I^2 \text{ joules} \quad (16)$$

by radiation; this result is independent of the length of the line or of its material; it depends only on the distance d between the two wires of the line. In this formula and in all the following, d is in centimeters and I in amperes.

Taking the same 100 km. transmission line as previously, and assuming only the d-c. resistance even during the transient conditions, it is seen that the energy wasted by radiation is only 1/10,000th of the energy wasted in heat during the time in which the line is being charged, and the steady d-c. conditions are reached. For a 1-km. line, the radiated energy would

FIG. 5

still be only one per cent of the energy wasted in heat during the transient conditions. The same remark as to the order of magnitude of the radiation compared to the joulian losses applies to all following examples.

2. A total *reflection* of a "rectangular wave" of current I at an *open* end of a line radiates⁹

$$4 d 10^{-9} I^2 \text{ joules;} \quad (17)$$

at a *grounded* end,

$$2 d 10^{-9} I^2 \text{ joules.} \quad (18)$$

In general, we have a *partial reflection* when the amount of current $K I$, (in magnitude and sign), is reflected and thus the rest of the wave is absorbed in the terminal apparatus. The radiated energy there is given by

$$3/2 (1 - 2/3 K + K^2) d 10^{-9} I^2 \text{ joules} \quad (19)$$

of which the three preceding formulas are particular cases. ($K = 0, K = -1, K = 1$)

3. A complete transposition, *i. e.* a sudden rotation

of 180 deg. of the plane of the wires of the line, produces a radiation of

$$6 d 10^{-9} I^2 \text{ joules,} \quad (20)$$

or four times as much as given by formula (15), because a transposition amounts to a sudden stopping of the current plus a sudden starting of the same current with opposite sign, in the same direction of propagation or to a sudden starting of twice the same current in the same direction, with opposite sign.

Hitherto, we considered a current flowing suddenly in the line at maximum value or a "rectangular wave" as we called it. Any other law for the current as a function of the time at the origin, as for example a sinusoidal law, can be assumed, with only changes in the calculations, but yielding the same conclusions as to the magnitude of the radiation effect.

We also neglected the influence of the ground and supposed a transmission line isolated in space. A perfectly conducting ground can be accounted for by taking with the line its image with respect to the ground; the resulting radiation is obviously less.

If, instead of considering disturbances between the two wires of a line, we consider disturbances between line and ground, the distance d between the wires would have to be replaced by twice the height of the line above the ground, in the case of a good conducting ground. This can magnify the radiation effect about twenty times, but keeps it still negligible compared to the effect of heat dissipation in the conductors.

CONCLUSIONS

The present conclusions settle the question of the relative unimportance of radiation in the attenuation and distortion of traveling waves along lines. They, however, leave the way open for the investigation of other more important causes of attenuation and distortion, among which we suggest the transient penetration of the current into the wire at the front of the disturbance, as mentioned above; the dissipation of energy in the ground due to the fact that some lines of force of a two-wire transmission line reach the ground and cause an attenuation as in the case of wireless waves; the non-homogeneity of the transmission line for high-frequency waves, *i. e.*, the slight periodic variations that occur in the constants of the line due to presence of poles and curved spans. The influence of changes in direction in the line, as far as radiation is concerned, can be found by the method employed here and is negligible.

SUMMARIZING

1. A criticism of the classical theory of propagation of traveling waves along a two-wire transmission line has been given showing that, as far as the shape of the wave near the front is concerned, this theory is still unsatisfactory.

2. Dr. Steinmetz's theory of the effect of radiation on traveling waves has been examined.

9. See note 5.

The curl components of E and H in the direction of the radius (see Fig. 3) are seen to be zero or of the second order, (*i. e.*, of the order of $1/r^2$), thus negligible. The components of curl E along a meridian line, and of curl H along a parallel line are obviously zero, because the vector is then perpendicular to the line of integration.

The component of curl H in the positive direction of a meridian line, (*i. e.*, towards the increasing θ), is given by

$$\text{curl}_\theta H =$$

$$- \frac{H(r + \Delta r) \cdot (r + \Delta r) \sin \theta \cdot \Delta \theta + H(r) \cdot r \cdot \sin \theta \cdot \Delta \theta}{\Delta r \cdot r \sin \theta \Delta \theta}$$

where $H(r)$ means the scalar value of H at the distance r . But we have, neglecting quantities of the second order, and using the value of H given by (1):

$$\begin{aligned} H(r + \Delta r) &= H(r) + \frac{\partial I}{\partial r} \cdot \frac{1 + \cos \theta}{\sin \theta} \cdot \Delta r \\ &= H(r) - 1/c \frac{\partial E}{\partial t} \cdot \Delta r \end{aligned}$$

Substituting in curl H , at the same approximation, we find the first equation of Maxwell.

The same procedure with regard to the signs leads to the second equation of Maxwell.

NOTE 4.

Formula (15) represents the energy carried to infinity by the spherical shell of variable depth

$$d \sin \theta \cos \phi$$

in which the value of the electromagnetic field is given, for $-\pi/2 \leq \phi \leq +\pi/2$, by formula (12)

$$E = H = I/2 \cdot \frac{1 + \cos \theta}{\sin \theta}$$

where I is the constant value of the suddenly impressed current. For $\pi/2 < \phi < 3\pi/2$, the sign of both E and H is to be changed.

At a given point on the sphere of (large) radius r , this electromagnetic field lasts during the time

$$|d/c \sin \theta \cos \phi| \quad (c \text{ speed of light})$$

the bars meaning a quantity that is positive.

The total energy radiated W will be given by the time integral extended over the sphere of radius r of Poyting's vector, which is directed everywhere along the radius outwards the sphere; *i. e.*

$$\frac{c}{4\pi} E \times H |d/c \sin \theta \cos \phi|$$

integrated over the sphere of which the element of area is

$$r^2 \sin \theta d\theta d\phi$$

We thus have to perform

$$W = \frac{c}{4\pi} I^2/r^2 \int_{\theta=0}^{\pi} \int_{\phi=0}^{2\pi} \left[\frac{1 + \cos \theta}{\sin \theta} \right]^2 |d/c \sin \theta \cos \phi| r^2 \sin \theta d\theta d\phi$$

But we have

$$\int_0^{2\pi} |\cos \phi| d\phi = 4$$

and

$$\begin{aligned} \int_0^{\pi} [1 + \cos \theta]^2 d\theta &= \int_0^{\pi} (1 + 2 \cos \theta + \cos^2 \theta) d\theta \\ &= \pi + 0 + \pi/2 = \frac{3\pi}{2} \end{aligned}$$

The value of W is thus

$$W = 3/2 d I^2 \quad \text{elmag C. G. S. units}$$

which is equivalent to (15).

NOTE 5.

The total reflection "with change of sign" of a rectangular wave of current at the free end of a line can be considered as the result of the stopping of the incoming wave $+I$ at the end, by starting at the end a new wave $-I$ along the same direction of propagation as that of the incoming wave, plus starting a new wave $-I$ in the opposite direction, *i. e.*, back into the line. This last wave is the wave "reflected with change of sign." The sign of a wave bears no relation at all to the direction of propagation.

The reflection at a free end of a line is thus equivalent to starting simultaneously two waves $-I$ from the end in two opposite directions. The electromagnetic field of such a double disturbance along a single wire is easily deduced from that given in formula (12), for a single disturbance. It is, with regard to the signs

$$\begin{aligned} E = H &= \frac{(-I)}{r} \frac{1 + \cos \theta}{\sin \theta} + \frac{(-I)}{r} \frac{1 - \cos \theta}{\sin \theta} \\ &= \frac{(-2I)}{r} \frac{1}{\sin \theta} \end{aligned}$$

$(-I)$ is the current started in both directions at the free end, equal in absolute value to the incoming current, and where the time t , of which I is a function in the general case, has been replaced by $t - r/c$, r being taken from the free end.

The case of a two-wire (transmission) line reduces to the preceding one as was seen. Thus, in the case of a rectangular wave of current along a line, the elec-

tromagnetic field due to the sudden starting at the end of the line of a current ($-I$) in both directions is:

$$E = H = -\frac{2\hat{I}}{r} \frac{1}{\sin \theta}$$

This field exists in a spherical shell of variable depth, $d \sin \theta \cos \phi$, expanding at the speed of light, as it has been shown. It lasts at a fixed point in space during the time

$$|d/c \sin \theta \cos \phi|$$

the bars meaning a positive quantity. The amount of radiated energy W can be found exactly as in the preceding note. We have:

$$W = \frac{c}{4\pi} \frac{4I^2}{r^2} \int_{\theta=0}^{\pi} \int_{\phi=0}^{2\pi} \frac{1}{\sin^2 \theta} |d/c \sin \theta \cos \phi| r^2 \sin \theta d\theta d\phi$$

what reduces immediately to:

$$W = 4dI^2 \quad \text{elmag c. g. s. units}$$

which is equivalent to formula (17).

In general, when the amount of current KI (in sign) is reflected into the line, the rest being absorbed in the terminal apparatus, we have for the electromagnetic field, with regard to the sign,

$$E = H = -\frac{\hat{I}}{r} \frac{1 + \cos \theta}{\sin \theta} + \frac{(KI)}{2} \frac{1 - \cos \theta}{\sin \theta},$$

which exists in a spherical shell of variable depth.

$$d \sin \theta \cos \phi$$

expanding at the speed of light.

The radiated energy is, as above,

$$W = \frac{c}{4\pi} I^2/r^2 \int_{\theta=0}^{\pi} \int_{\phi=0}^{2\pi} \left[\frac{(1-K) + (1+K) \cos \theta}{\sin \theta} \right]^2 |d/c \sin \theta \cos \phi| r^2 \sin \theta d\theta d\phi$$

The value for W follows

$$W = 3/2 (1 - 2/3 K + K^2) dI^2 \text{ elmag. c. g. s. units}$$

which is equivalent to (19).

NOTE 6.

The position of the point X_1 , limiting the length $X_1 X_2$ (Fig. 5) along which the two spherical shells can have parts in common is determined by the intersection of a circle of radius r centered upon O_1 , and of a circle of radius $r-l$ centered upon R_2 , r being very large compared to l . This allows to approximate the circles by parabolas of the same curvature, *i. e.*, of which the parameter p is equal to the radius of the circles; the axis of the first parabola will coincide with the wire

$O_1 R_1$, the axis of the second with the wire $O_2 R_2$. We so have

$$y-d = \sqrt{2(r-l)x} \quad \text{Par. 2}$$

$$y = \sqrt{2rx} \quad \text{Par. 1}$$

with obvious axis of coordinates. Calling (ξ, η) the coordinates of the point X_1 , we deduce

$$\eta = \sqrt{\frac{r}{r-l}} \cdot \sqrt{2(r-l)\xi} = \sqrt{\frac{r}{r-l}} (\eta-d)$$

As ξ is very small, η is the distance of X_1 to wire 1—We have thus, from the preceding equation, neglecting the square and higher powers of r/l :

$$\eta/r = 2d/l.$$

which proves that, viewed from a point of the line, the length $X_1 X_2$ does not cover an angle larger than

$$\frac{4d}{l}, \text{ provided } l \text{ is small compared to } r.$$

Hence, calculating the energy radiated by the two spherical shells in contact as if they were not in contact, *i. e.*, integrating over π instead of π minus the angle η/r , will introduce only an error of the order of d/l , thus quite negligible.

Discussion

V. Karapetoff: On the second page of Dr. Manneback's paper, on the top of the second column, three conclusions are drawn. The first conclusion is that: "An electric disturbance, *i. e.*, a discontinuity of voltage or current, is always propagated along any line at the constant speed $V = 1/\sqrt{LC}$." And then he adds: "whether there is resistance and leakage or not". I am not sure that this is correct; it seems to me that the velocity of propagation depends on the presence of resistance and leakage and is thereby reduced.

Then, coming to the page on which is Fig. 2, in the second column there is an integral which represents the energy radiated, and this energy is expressed by a finite formula. In Peirce's book on "Electric Waves and Oscillations," in a simpler case of an antenna, a similar result is expressed in the form of an infinite series; and I should like to know just where the difference lies and why in this case a finite expression is possible.

In the treatment of transient radiation on the page on which Fig. 3 is placed, the principle of super-position is used, and I wonder if much of the mathematics in the preceding case of static conditions could not be eliminated by also using the principle of super-position in this form. We already have a formula for energy radiation from a single antenna. Since in this article the effect of the ground is neglected, it does not make any difference whether the transmission line is horizontal or vertical, so suppose we place it vertically. Then the transmission line is analogous to two antennae placed side by side and electrically subjected to disturbances at 180 degrees in time lag. Therefore, if one should write equations for radiation from one antenna and then take a finite difference for the other antennae, one should get the correct result. Since Dr. Manneback does this for the transient condition, I should like to know why it could not be for the static condition as well.

Joseph Slepiant: I was very much interested in the paper by Mr. Manneback because there has been in the last year something of a dispute in the pages of our JOURNAL between such eminent authorities as Dr. Steinmetz and Dr. Carson as

to whether there is really any radiation from a traveling wave on a transmission line. This paper I believe supports Dr. Carson's contention that there is no such radiation. A casual reader might believe that the conclusion of this paper is that there is a radiation but only a small one. However, Dr. Manneback shows that this small radiation is due to ohmic loss, reflections, or anything which prevents the wave from freely traveling and that a freely traveling wave does not radiate energy.

I would like to give an argument for this last conclusion based on a principle of relativity. The principle I shall use is this: that an observer moving with an object both at uniform and the same velocities sees nothing different in that object over what he would see if both he and the object were at rest. This is true whether the body is electrically charged or not. Now a freely traveling wave on a transmission line consists of a charge moving with uniform velocity. So far as electrical effects go it is the same as if a charged material object were moving with uniform velocity. An observer moving with this charged object would see nothing different from what he would see if both he and the object were at rest. If both he and the object were at rest we know that there would be no change and no loss of energy from the object by radiation. We must therefore conclude that in the case of the uniformly moving charged object there is also no radiation of energy.

V. Bush: Recent progress in radio communication has focused the attention of engineers upon the radiation characteristics of electrical circuits. All a-c. circuits radiate to a certain extent; that is there is a loss in any such circuit, which is caused by the production of waves carrying energy off into space. The filament of an incandescent lamp has a certain small amount of input, over and above that consumed by ohmic losses, which is necessary to provide the energy radiated as heat and light. The radiation from a lamp is caused by the temperature of the filament; that is by the rapid oscillatory heat motion of its electrons. When an alternating current flows in a circuit, the electrons move comparatively slowly back and forth along the conductor. They radiate in each case in exactly the same manner. The waves from the lamp are very short, while those from an alternating or oscillating circuit are very long; but otherwise they are the same sort of waves. When a circuit is designed to radiate a large fraction of its input, it is called an antenna. The length of the waves produced from a circuit depends upon the frequency existing in the circuit. From a 60-cycle circuit, the waves will be 5,000,000 meters or 3100 miles long. The radiation per volt or per ampere from a given circuit varies as the fourth power of the frequency. Hence, at commercial frequencies radiation is ordinarily entirely negligible. An antenna which radiates 100 kw. at a radio communication frequency of 30,000 cycles per second would radiate only 1.6 microwatts if excited to the same potential at 60 cycles. Thus we can ordinarily disregard the effect in our power networks as far as loss of power is concerned.

At high enough frequency, a transmission line may radiate appreciable energy. It becomes a sort of loop antenna. This has been made use of in radio telephone systems for transmission lines, where the line is caused to act as a carrier of the very high-frequency waves which serve the telephone. These waves may be placed on and taken from the transmission line by isolated terminal radio apparatus making use of the radiation characteristics of the line.

It is natural, therefore, to inquire what part radiation plays in the progress of transients of various sorts over transmission lines. Is the abruptness of a switching transient greatly modified by radiation of part of its energy from the line? We know that the steep wave front of such a transient involves rates of current and voltage change corresponding to the rates found at very high frequencies. Is the radiation large as a consequence?

The attack on this problem is attended by one prominent

difficulty. Much has been written, particularly of late and by radio engineers and physicists, concerning the radiation from circuits of various sorts, and some of this analysis has been experimentally checked. Practically all of it, however, refers only to the steady state, after transient conditions in the system have entirely died away. It is the effect during the transient period that we wish to examine. Radiation during transients has been little treated except in the classics, and there not for the cases which most interest us from the practical standpoint.

In fact, the very definition of the radiation during a transient is a matter of some concern. Radiation in the steady state is easily defined. When steady alternating potential and currents exist in a circuit, they are accompanied by steady electrostatic and electromagnetic fields surrounding the circuit. These fields constitute a storage of energy. When a field collapses, the stored energy largely returns to the circuit, but not all of it returns. Some of the energy stored in one half-cycle does not return during the next half-cycle. This residual of energy is the energy of the radiated wave, which proceeds out from the circuit at the speed of light. The power radiated from a circuit in the steady state is the energy lost per second in this manner.

In the transient state, we suddenly establish, or remove, potentials and currents. This means the establishment, or removal, also of electrostatic and electromagnetic fields. What portion of the energy represented by the fields thus set up or destroyed shall be considered as radiated energy? When a current is suddenly caused to flow in a circuit, the accompanying magnetic field appears first in the immediate vicinity of the wires. This field then rapidly spreads outward at the speed of light, and finally a field will be produced to indefinite distances. If, while this field is spreading, we examine it mathematically, we find that there is a flow of energy outward. The front of the disturbance carries outward the energy, and spreads it over space as it goes. But if we examine the expression for the total energy in this front of disturbance, we find that it does not tend to zero as the disturbance proceeds to infinity, but approaches a definite finite value. Over and beyond the energy stored in the field, there is thus carried outward an additional amount which moves off indefinitely and is lost forever from the circuit. It is this energy which is the energy radiated during the transient.

In this paper, Dr. Manneback examines the amount of energy thus radiated from a transmission line of usual size and form, where steep transients are involved. He treats the progress of rectangular waves during reflections and at transpositions of the line. The results may be very simply summed up. To engineering accuracy the effect of this radiation may be, without error, ignored in analysis, where the progress of a single steep wave is concerned.

This does not mean, of course, that radiation is always negligible in connection with a transmission line. It indicates only that we cannot depend upon this factor for assistance in reducing its effect of single steep transients. When, for instance, we close a switch at one end of a long line producing a wave which travels down the line and impinges upon the transformer at the distant end, radiation will very little diminish the severity of the impact. If, on the other hand, an arc to ground under certain conditions sets up a steady state of very high-frequency waves, then the effect of radiation may be considerable and very welcome.

The transmission engineer does not deal, after all, simply with a few long wires in which current flows. The effects which he produces and utilizes are spread all over surrounding space. A comprehensive analysis must then deal not only with effects in and between the wires, but also with those fields which are propagated outward from the system. Circuits are, strictly speaking, always three dimensional.

CORRESPONDENCE

PROPAGATION OF DISCONTINUITIES OF THE FIRST DERIVATIVE OF VOLTAGE AND CURRENT ALONG AN ELECTRIC LINE

To the Editor:

IT has been proved by the writer¹ that a discontinuity of the magnitude of voltage or current is always propagated along any electric line at the velocity of light in the surrounding medium ($v = 1 : \sqrt{LC}$), whether or not there is resistance and leakance present. It has been asked by Dr. Bush if it is not true that this discontinuity of voltage or current may be either a discontinuity of magnitude or simply of derivative. Thus, if a sinusoidal voltage is applied to a long transmission line at the zero of voltage, the discontinuity which travels has no steep wave front; what is propagated in this case is a discontinuity of derivative only of voltage and current. There is no doubt about this discontinuity being also propagated along any line at the velocity of light, whether or not there is resistance and leakance. The following may be a proof for it.

The voltage V and the current I along a line are connected together by the well-known equations, where R, L, G, C represent the four constants of the line as usual:

$$L \frac{\partial I}{\partial t} + RI = - \frac{\partial V}{\partial x} \quad (a)$$

$$C \frac{\partial V}{\partial t} + GV = - \frac{\partial I}{\partial x} \quad (b)$$

By eliminating V or I between these equations, the same equation of propagation is obtained for V and I . (equation 1 in paper.)

Let us consider a point $M(x, t)$ along the line, at which V and I are continuous functions of x and t , but where $\partial V / \partial x$ is a discontinuous function of x . Let this discontinuity be propagated at an unknown velocity v . We will show that v must necessarily be equal to $1 : \sqrt{LC}$. After the time Δt has elapsed, the discontinuity will have traveled from $M(x, t)$ to $M'(x + v \Delta t, t + \Delta t)$. Let us express the fact that the voltage V , which is continuous at M , is still continuous at M' . Calling V_1 and V_2 the values of the voltage left and right of M and infinitely near this point, we have

$$V_1 = V_2$$

$$\text{at } M' \quad V_1 + \frac{\partial V_1}{\partial x} \cdot v \Delta t + \frac{\partial V_1}{\partial t} \Delta t$$

$$= V_2 + \frac{\partial V_2}{\partial x} \cdot v \Delta t + \frac{\partial V_2}{\partial t} \Delta t$$

$$\text{hence,} \quad v \bar{V}_x + \bar{V}_t = 0 \quad (c)$$

denoting by $\bar{V}_x$ the discontinuity of the space-deriva-

tive of the voltage at $M(x, t)$, i. e., $\partial V_2 / \partial x - \partial V_1 / \partial x$, and by $\bar{V}_t$ the discontinuity of the time-derivative of the voltage at the same point $M(x, t)$, i. e., $\partial V_2 / \partial t - \partial V_1 / \partial t$. It is seen from (c) that when a discontinuity $\bar{V}_x$ exists at a point $M(x, t)$, it is necessarily accompanied by another discontinuity, $\bar{V}_t$, at the same point $M(x, t)$.

Let us now assume that V is continuous at M . We have as above $V_1 = V_2$. By means of (b), this becomes

$$C \frac{\partial V_1}{\partial t} + \frac{\partial I_1}{\partial x} = C \frac{\partial V_2}{\partial t} + \frac{\partial I_2}{\partial x}$$

where I_1 and I_2 denote the values of I left and right of M and infinitely near this point. Using for the derivatives of I notations similar to those used for V , we get from the preceding equation

$$C \bar{V}_t + \bar{I}_x = 0 \quad (d)$$

which shows that a discontinuity of V/t at the point $M(x, t)$ entails a discontinuity of I/x at the same point $M(x, t)$.

Similarly, assuming that I is continuous at M and using equation (a), we obtain

$$L \bar{I}_t + \bar{V}_x = 0 \quad (e)$$

which shows that a discontinuity of $\partial V / \partial x$ at the point $M(x, t)$ entails a discontinuity of $\partial I / \partial t$ at the same point $M(x, t)$.

Expressing finally, as we did for the voltage, that the current I , which is continuous at $M(x, t)$, is still continuous at $M'(x + v \Delta t, t + \Delta t)$, we get similarly

$$v \bar{I}_x + \bar{I}_t = 0 \quad (f)$$

which connects the two discontinuities of I at the same point.

There are thus four homogeneous linear equations (c, d, e, f) connecting the four discontinuities $\bar{V}_x, \bar{V}_t, \bar{I}_x, \bar{I}_t$. In order that the system of equations may be compatible, the following relation must be verified

$$\begin{vmatrix} v & 1 & 0 & 0 \\ 0 & C & 1 & 0 \\ 1 & 0 & 0 & L \\ 0 & 0 & v & 1 \end{vmatrix} = 0$$

or, developing the determinant,

$$v^2 LC - 1 = 0.$$

This shows that the velocity of propagation v of a discontinuity of the derivative $\partial V / \partial x$ is necessarily equal to $1 : \sqrt{LC}$, which is the velocity of light in the surrounding medium. Moreover the four above equations prove that, V and I being continuous functions of x and t , the mere existence of a discontinuity of any one of the derivatives of V and I at a point $M(x, t)$ entails the existence of discontinuities of the three other derivatives at the same point $M(x, t)$. They are all propagated together at the same velocity v .

The discontinuity of voltage which is produced when a sinusoidal voltage is impressed on a long transmission line at the zero of voltage is a particular case of the preceding.

A New Equation for the Static Characteristic of the Normal Electric Arc

BY W. B. NOTTINGHAM

Associate, A. I. E. E.
Fellow of the American-Scandinavian Foundation

COMMERCIALLY the electric arc is now extensively used, and yet after more than a hundred years of study, there has been little crystallization of opinion as to certain phases of its fundamental theory. Absolute contradictions are frequently found in the literature, and premature generalizations have given rise to more disagreement among the investigators of the equation of the static characteristic of the normal¹ arc than the experimental difficulties warrant.

The static characteristic is the relation between the current (i) flowing in the arc, the length (L) of the arc, and the difference in potential (E) across the arc. This relation can be represented approximately by simple expressions of the form of the Ayrton² equation

$$E = a + b \cdot L + \frac{c + d \cdot L}{i} \quad (1)$$

or the Steinmetz³ equation

$$E = a + \frac{c(L + d)}{i^{0.5}} \quad (2)$$

(a , b , c , and d are constants)

if the range in variation of the current and arc length, for which the constants are calculated, is the closely defined.

In particular, these equations are recognized as approximations, because *the difference in potential (E) is not a linear function of the arc length (L)*, and although the difference in potential does decrease when the current increases, *the current (i) enters neither as the first power (as in the Ayrton equation) nor as the square root (as in the Steinmetz equation)*. Duddell⁴ was among the first to demonstrate by the use of the

1. Each stage of the electric arc from the glow arc to the hissing arc has its own physical, electrical and chemical characteristics. Therefore any equation of the electric arc must necessarily be limited to the characteristics of one stage. The normal arc has two general requirements: (1) the current intensity must be greater than the maximum for the glow arc, and less than the minimum for the hissing arc; and (2) the arc must be free from external electrical, magnetic, atmospheric, and physical disturbances.

curve shown in Fig. 1, that, for arcs less than 15 mm. in length, the difference in potential cannot possibly be truly represented by a linear function of the arc length. As far as I know, Steinmetz⁵ was the first to advance the thesis that, "while the stream voltage varies with the current, and in the opposite direction

Fig. 1

to it, its variation is much less than the inverse proportion to the current."

This paper attempts to make these two criticisms constructive or positive instead of negative.

THE EXPONENT OF THE CURRENT IS DIRECTLY PROPORTIONAL TO THE TEMPERATURE OF THE BOILING POINT OF THE ANODE

If the arc length is assumed to be constant, the

FIG. 2—VOLT-AMPERE CHARACTERISTICS WITH THE ARC LENGTH CONSTANT $L = 3.0$ MM.

Ayrton and the Steinmetz equations can be written in the form of equation (3)

$$E = A + B/i^n \quad (3)$$

5. See foot-note 3.

the relation between the arc length and the difference in potential. The substitution of the values:

$$C = 28.0, \quad D = 42.5, \\ \gamma = 5.0, \quad \delta = 0.373, \\ d = 6.0,$$

in equation (8) gave (9).

$$E = 28.0 (1 - e^{-6L}) + 42.5 (1 - e^{-0.373L}) + 5.0 \cdot L \quad (9)$$

TABLE IV
THE COMPARISON BETWEEN THE OBSERVED AND THE CALCULATED VALUES OF E

Electrodes—Copper; Current—1.0 Ampere

0.02	6.0	3.20	+ 2.40	- 1.50
0.04	10.0	6.20	+ 3.80	- 0.20
0.10	17.0	14.64	+ 3.36	- 0.44
0.20	26.0	23.60	+ 2.40	+ 0.60
0.30	31.0	31.50	- 0.50	- 1.30
0.50	37.0	36.32	+ 0.68	+ 0.58
0.70	42.0	40.90	+ 1.10	+ 1.10
1.0	46.0	45.97	+ 0.03	+ 0.03
2.0	60.0	60.30	+ 0.30	+ 0.30
3.0	71.5	71.60	- 0.10	- 0.10
4.0	81.0	81.00	0.00	0.00
5.0	89.0	88.90	+ 0.10	+ 0.10
6.0	96.0	95.90	+ 0.10	+ 0.10
7.0	102.0	102.20	- 0.20	- 0.20
8.0	108.0	108.20	- 0.20	- 0.20
10.0	120.0	119.50	+ 0.50	+ 0.50

11. See footnote 10.

The difference in potential as observed and that as calculated by equation (9), have been placed in parallel columns in Table IV. The error (Δ) between the observed and the calculated values, is well within that attributable to experimental variations.

FIG. 5—VOLT-ARC LENGTH CHARACTERISTIC FOR DIFFERENT CURRENT VALUES

If the current is infinite equation (3) becomes

$$E = A = f(L) \quad (10)$$

Therefore, the curve showing the relation between the arc length and the constant A can be called the "infinite

current" curve. (See Fig. 5.) Equation (8) represents this curve if the constants are assigned the following values:

$$C = 14.5, \quad D = 15.5, \\ \gamma = 1.7, \quad \delta = 0.235, \\ d = 6.0,$$

Hence, the second curve studied can be approximated very closely by equation (11). (See Table V.)

$$E = 14.5 (1 - e^{-6L}) + 15.5 (1 - e^{-0.235L}) + 1.7 L \quad (11)$$

TABLE V
THE COMPARISON BETWEEN THE VALUES OF A AS DETERMINED FROM EQUATION (3) AND THAT CALCULATED BY EQUATION (11)

Electrodes—Copper Current—Infinite
 A Determined by Equation (3)
 A_c Calculated by Equation (11)

Arc Length L mm.	Determined A Volts	Calculated A_c Volts	Error Volts
1.0	19.6	19.43	+ 0.17
2.0	23.7	23.71	- 0.01
3.0	27.5	27.48	+ 0.02
4.0	30.8	30.74	+ 0.06
5.0	33.8	33.74	+ 0.06
6.0	36.5	36.40	+ 0.10
7.0	39.0	38.90	+ 0.10
8.0	41.3	41.23	+ 0.07
10.0	45.5	45.52	- 0.02

The numerical values of C , D , γ , δ , and d were also determined for each of the remaining curves in Fig. 5, and these values were plotted as functions of the current. In this way, it was discovered that d is independent of the current and that C , D , γ , and δ are functions of the current of the form of equation (12)

$$f(i) = a + \frac{b - a}{i^n} \quad (12)$$

In equation (12), a is the value of the constant when the current is infinite and b , the value when the current is 1.0 ampere. Therefore, in the case of the arc between copper electrodes, the constants of equation (8) may be expressed as functions of the current as follows:

$$C = 14.5 + \frac{28.0 - 14.5}{i^{0.67}} \quad (13)$$

$$D = 15.5 + \frac{42.5 - 15.5}{i^{0.67}} \quad (14)$$

$$\gamma = 1.7 + \frac{5.0 - 1.7}{i^{0.67}} \quad (15)$$

$$\delta = 0.235 + \frac{0.373 - 0.235}{i^{0.67}} \quad (16)$$

$$d = 6.0 \quad (17)$$

The substitution of the above functions in equation (8) gives (18), the desired final equation for the arc between copper electrodes.

$$E = \left(14.5 + \frac{28.0 - 14.5}{i^{0.67}} \right) (1 - e^{-\epsilon \cdot L})$$

$$+ \left(15.5 + \frac{42.5 - 15.5}{i^{0.67}} \right) (1 - e^{-(0.235 + \frac{0.373 - 0.235}{i^{0.67}}) L})$$

$$+ \left(1.7 + \frac{5.0 - 1.7}{i^{0.67}} \right) L \quad (18)$$

As an indication that equation (18) is the characteristic equation sought, eighty-eight calculated values of the difference in potential have been placed beside the corresponding observed values in Tables IV and VI. Tables IV and VI indicate that equation (18) does fit these data without systematic error. However, if apparatus had been available for the study of arcs more than 10.0 mm. in length, the constants of equation (18) could no doubt have been determined with a higher degree of accuracy.

and for infinite current. For the curve for 1.0 ampere, let

$$C = \alpha_1, \quad D = \beta_1, \\ \gamma = \gamma_1, \quad \delta = \delta_1, \quad \text{and} \\ d = d$$

and for the curve for infinite current, let

$$C = \alpha_\infty, \quad D = \beta_\infty, \\ \gamma = \gamma_\infty, \quad \delta = \delta_\infty, \quad \text{and} \\ d = d$$

These constants incorporated in a general equation give equation (19).

$$E = \left(\alpha_\infty + \frac{\alpha_1 - \alpha_\infty}{i^n} \right) (1 - e^{-d \cdot L})$$

$$+ \left(\beta_\infty + \frac{\beta_1 - \beta_\infty}{i^n} \right) (1 - e^{-(\delta_\infty + \frac{\delta_1 - \delta_\infty}{i^n}) \cdot L})$$

$$+ \left(\gamma_\infty + \frac{\gamma_1 - \gamma_\infty}{i^n} \right) \cdot L \quad (19)$$

Although equation (18) is an empirical equation derived as a result of the study of the arc between copper electrodes, it can be expressed in general terms and used to represent the static characteristic of any arc. It will be remembered that n was the first constant in equation (18) to be determined. This determination also yielded the values of A from which the curve for infinite current was plotted. (See equation (3) and Fig. 5.) The constants of equation (8) were then determined for the curves in Fig. 5 for 1.0 ampere

EQUATION (19) TESTED FOR TEN ELECTRODE MATERIALS

All of the constants of equation (19) were calculated for the ten arc combinations studied and the resulting equations were checked graphically against the observed data. (See Table VII.)

The agreement between the observed and the calculated values was exceedingly close in every case. Therefore, equation (19) is undoubtedly a truly general equation

In equation (22),

$$A = \alpha_{\infty} + \beta_{\infty}, \quad B = \gamma_{\infty},$$

$$C = \alpha_1 - \alpha_{\infty} + \beta_1 - \beta_{\infty}, \text{ and } D = \gamma_1 - \gamma_{\infty}$$

Although the results of this study are illuminating, they only point the way. A more extensive investigation of the arc in different atmospheres and at different pressures should be undertaken in hope that this equation, or some modification of it, will offer a method by which the arc characteristic can be studied in its component parts without the introduction of an exploring electrode. The equation might then be used to solve the many problems involving the distribution of the power consumption in the arc and the problem of determining the temperature in the arc, which now confronts the investigators of commercial arcs employed for the fixation of nitrogen, arc lighting, the electric furnace, etc.

CONCLUSIONS

1. The exponent n of the current i in the equation

$$E = A + B/i^n \quad (3)$$

is directly proportional to the absolute temperature of the boiling point or the sublimation point, as the case may be, of the anode.

2. Equation (19) can be made to represent the static characteristic of the normal arc without apparent systematic error.

$$E = \left(\alpha_{\infty} + \frac{\alpha_1 - \alpha_{\infty}}{i^n} \right) (1 - e^{-d \cdot L})$$

$$+ \left(\beta_{\infty} + \frac{\beta_1 - \beta_{\infty}}{i^n} \right) \left(1 - e^{-(\delta_{\infty} + \frac{\delta_1 - \delta_{\infty}}{i^n}) \cdot L} \right)$$

$$+ \left(\gamma_{\infty} + \frac{\gamma_1 - \gamma_{\infty}}{i^n} \right) \cdot L \quad (19)$$

3. Arcs more than 15.0 mm. in length can be represented accurately by the equation

$$E = A + B \cdot L + \frac{C + D \cdot L}{i^n} \quad (21)$$

I wish to acknowledge my indebtedness to the American-Scandinavian Foundation whose fellowship made this work possible, and to Professor Gustav Grandqvist of Uppsala, Sweden and Mr. P. P. Cram for their assistance in the preparation of paper.

APPENDIX

The Description of the Apparatus. The electrodes were 12 mm. in diameter and made of the very highest grade of materials. After each reading the electrodes were refaced to insure precision in arc length measurements and to reduce the meter fluctuations to a minimum. The upper electrode was the anode except in the cases of the cadmium, antimony, bismuth and lead arcs.

Loosely fitting jackets supplied by independent water systems, were used to carry the excessive heat from the electrode supports. Readings taken with and with-

out these jackets showed that this slight cooling had no appreciable effect on the arc characteristic.

For the longer arcs, the length was determined by the measurement of the image of the arc produced by a lens system (magnification 15 diameters) on a scale calibrated to read arc length directly in millimeters. The short arcs were adjusted by a micrometer screw.

The arc was freely open to the air at all times.

The Observed Data. The principal data from which the constants of the equations were calculated, are recorded in the following tables, I to X inclusive.

forbidden to us before. The development of a revised mathematical treatment may thereby however become far more difficult, as the simple short cuts of Maxwell may then no longer be applicable.

The paper is intended merely to open up the subject and to make suggestions for a revision; it is not intended to be a completed and finished treatise on the subject. It is hoped some others with better facilities for research will find enough of interest and value in the experiments and in the suggestions to continue the investigations more thoroughly and perhaps to offer different and better interpretations and deductions from them.

If no unquestionable errors can be found in the proposed revision, the chief subject of discussion should be, whether the proposed revision would or would not have any advantages over the older system and this of course is a matter of opinion. It is of no consequence that it may be possible to explain some of the writer's experiments by means of the old laws, the important question is, which explanation is the more rational one and which is the better one for the student to grasp. The fact that the development of a corresponding mathematical treatment may then become far more difficult, ought not to be an insurmountable objection. Some of the points involved were recommended by Faraday and by Ampere, but they were discouraged by Maxwell; they did not fit in well with his mathematical short cuts.

THE PHYSICIST AND THE ENGINEER

It is the province of the physicist to discover and formulate the laws of nature concerning matter and energy and to develop the mathematical relations; and it is the province of the engineer to then take these laws and apply them to the benefit of mankind; the present subject therefore more properly belong under physics. During the past fifteen years the writer has repeatedly called the attention of physicists to the experimental evidence of the present unsatisfactory state, and showed how some of our laws have misled and even deceived the engineer when he tried to apply them; they were repeatedly appealed to by the writer to revise them so that the engineer could use them and depend on them as being correct. But not only was there no response (with one notable exception, the development of the quantitative relations by Northrup, concerning the "pinch effect," which has been of great value) but there was a surprising lack of interest in correcting alleged mistakes and shortcomings, and even a determined effort to prevent the publication of the writer's investigations. In one case publication was at first refused on the ground that if the experimental evidence was correct, which was easily demonstrated, it was so serious a matter to change one of the older laws, that it ought to be kept a secret! In another case the refusal was because it was, "so subversive of long established principles," the age of a law being considered more important than its correctness. Both papers however have been published.

The invention of a new and special definition of a sliding contact, to make an exception still fit an old law, seemed to be quite satisfactory to many physicists. Their attitude was that the older laws "were good enough for them." To make misfits fit, some have alleged that a circuit which was in fact open must be considered as being closed; others, that one which was in fact closed must be considered as being open. Their students have the sympathies of the writer, especially as one of the first things they learn in the laboratory is the sometimes very serious physical difference between an open and a closed circuit.

On account of this strange neglect, lack of interest, and even opposition of the physicist, which was not a credit to his profession, to provide the engineer with laws that are reliable and up to date, the writer must now appeal to the electrical engineers among whom there are some physicists of a more progressive class. The laws of physics are the engineer's most important tools; if their makers refuse to make proper tools for him he must make them himself.

MOTIONS OF MOBILE CONDUCTORS

By passing currents, especially at high current densities, through such very mobile metallic conductors as mercury or molten metals in some types of electric furnaces, the writer many years ago noticed the existence of some heretofore unrecognized electromagnetic forces which tended to move the conductors, and being mobile liquids they responded much more readily to such forces than solid conductors do.

Some of these new forces were very formidable, for like most of such forces they presumably increase with the square of the current. The writer then made use of them in electric furnaces many of which are in daily use, these new forces being the absolutely essential factor, showing their industrial importance.

Arcs also respond readily to some of these forces.

LAWS NEED REVISION

Not only were there these new forces, but that gospel faith in the reliability of laws which the engineer ought to be able to have, led the writer in two notable cases to waste time and money before finding out that the laws had not been correctly stated. These experiences gave rise to the present investigation which developed similar results with other laws.

It will be shown below how some of the older laws sometimes mislead, leading us away from rather than toward the true goal; others apply ambiguously, or even specify results quite the contrary to the facts. Some supposedly universal ones (that is, having no exceptions) were found not to be so, thereby having checked possible progress. Some were not based on their true fundamentals but on mere incidental factors; some which apply correctly to special cases have been applied to the more general case, which process may lead to serious errors. In a mathematical treatment it is important to select the best fundamental, which has

not always been done; thus if the mathematics of something circular, like a soap bubble film, is based on the radial pressure, the formula fails for the tension of a plane film, giving infinity, which is not true; while if based on the tension of a plane film the internal pressure in a bubble may be determined from it. Our unit of current is based on the magnetic force of a circular circuit. A closed finite line had better be made a special case of an infinite straight line, than the reverse.

In going from the general to a special case some factors generally drop out and can never again reappear in any subsequent deductions from the mathematical treatment of this special case. Or if a mathematical treatment is started for a case which is really a special and not the fundamental one, it is an error to apply it to the more fundamental one, or to other special cases in which the dropped factors may be different. Yet it seems such mistakes have been made. In a complicated system it is therefore important to find or select the best and most basic fundamentals.

A revision of our former laws is also desirable now that it is known that every electric current is merely a movement of electrons in the conductor. In Fig. 1, if negative electrons pass from one body *A* to another

B, through a conductor *C*, what we call a current flows through that conductor during that passage, creating simultaneous magnetic effects *m*, *m*, around it, each caused by its moving electron *e*, *e*; after the operation the body *A* is left charged positively and *B* negatively. Telegraph messages have been sent by currents in such a conductor, after an aurora borealis. It is therefore no longer an absolute necessity to consider every electric circuit as being a "complete circuit;" in many cases it is a great convenience to do so, a short cut, but in some it misleads and involves great difficulties to make it fit the facts; a law to be universal should therefore not be based on the circuit being a complete one. The complete circuit should better be made a special case of a unit length of a straight circuit. Ampere advocated basing the mathematical treatment on elemental parts of circuits, but Maxwell did not approve it, preferring the easier method or short cut based on the complete circuit, which however is a special case and not the most general one.

When two current carrying conductors are in some parts quite near to each other as at *a b* Fig. 2, and at other parts far apart, the force between them will reside almost entirely in the near parts *a b*; in practise this force would be practically the same whether the rest of the circuits are a foot or a mile long. In engineering work the consideration of the "rest of the circuit" is generally quite unnecessary; the leads to a

motor do not electromagnetically affect the mechanical forces in the motor.

The present tendency to abandon that useful stepping stone, the ether, also makes it desirable to revise some of our former conceptions. A magnetic field in space was thought to be a storage of energy in the form of a sort of stress or strain in the surrounding ether, which was and is still a very convenient and useful picturization. It seems to be much better, however, to consider the magnetic field around a current-carrying conductor to be merely an action at a distance, as Faraday proposed, the seat and source of the force being in the material of the conductor and not in the space around it; no assumption of any ether is then necessary. The reaction of these external forces on each other or on a foreign force, must then manifest itself in the material of the conductor through which the electrons are passing, and at the places where these forces are originated by them.

It is therefore the conductor itself, that is, the matter in it, which had better be referred to in these laws and not the more subtle currents, circuits, fields or ether. Experiments illustrating this will be described below.

It is also our duty to the student and the rising generation to point out any errors and exceptions and to revise the laws, conceptions and explanations so as to make them the simplest and clearest possible in order that they may be grasped and retained as easily as possible. Complicated conceptions and explanations such as many of those for sliding contacts, are objectionable. Above all, the laws should be strictly correct, should not mislead and should if possible be universal.

MISTAKES IN SOME LAWS

The elementary law given in every text book, that like currents attract and unlike repel, is wrongly worded; it is not on the currents but on the material of the conductor that these forces act. If they acted on the currents then the current density would have to be greater in the center of a conductor than near the outside, and Ohm's law would no longer apply to large conductors; or when two conductors are close to each other the current densities in different halves of the same conductor would have to be different; or the current in the middle of a cathode or anode in an electrolytic bath would have to be greater than elsewhere. But we know these are not the facts. Moreover like cathode rays repel. The industrially important pinch effect¹ would not exist, yet we know it does. Maxwell (Art. 501) recognized and called attention to this important distinction between the current and the conductor, but many of his followers did not. Nor did Maxwell continue to make a similar

1. Considering a conductor as consisting of a bundle of filamentary ones, this force tends to make them move to the center. When the conductor is a liquid the material is free to move and these radial forces may then become great enough to cause rupture. This phenomenon has been called the pinch effect. See bibliography at end of this paper.

distinction in his law of induction (Art. 531) as he ought to have done.

In a paper before this Institute (TRANS. Vol. 27, Part 2, 1908 p. 1341) the writer described a simple experiment showing conclusively that a similar distinction must also be made in Maxwell's law of induction. It is the conductor, that is, the matter and not merely the circuit, which must cut the magnetic flux in order to induce a current; if the circuit alone cuts it, the conductor remaining stationary with respect to the flux, there will not be the slightest induction even though exactly the same linkages of the flux and the circuit have taken place. (See also a modification of Faraday's experiment in the *Jour. Frank. Inst.* Nov. 1, 1921 p. 605). This important law therefore also requires revision. It moreover also fails to show in what part of the circuit the induction actually takes place and therefore what parts are dead or inactive, which is sometimes of importance to know.

The writer maintains that just as in the two cases mentioned above, it is necessary to make a similar distinction between the conductor itself and the magnetic field surrounding it. The forces in this field have their seat and origin in the material of the conductor where the electrons are passing through it; which should therefore be their anchorage or abutment; any actions of these forces on each other or on a foreign force should, therefore, have their reaction in the conductor. If a large heavenly body passed through the field of force of gravity between this earth and the sun, the abutments of the new gravity forces would be in the earth and the sun, not in the space between them. It is difficult to conceive how the abutment of an electromagnetic force could be in the ether; the energy in the cases here referred to is not a radiated wave motion.

In other words the flux around a conductor or magnet should be pictured as though it were in some way elastically attached to the material in which its source lies. Faraday entertained this idea (*Exp. Res.*, Vol. 2; p. 293; Vol. 3; p. 447), as pointed out by Maxwell (Art. 529) when the latter says: "He even speaks of lines of force belonging to a body as in some sense part of itself, so that in its action on distant bodies it cannot be said to act where it is not." Maxwell however does not favor the idea of action at a distance (Art. 552).

A distinction should here be made between a field of force or a storage of energy, which remains with the source, such as in most electromagnetic machinery, and one which leaves it completely as by radiation, such as in wireless transmission. In the latter case the forces acting in such fields of energy do not react on the source; when a bullet hits a target or is deflected, the forces on it do not react on the gun. The present discussion refers only to fields of force or energy which remain with their source.

One of the most common of the older laws concerning the production of motions by a circuit is to the effect that a circuit will produce such motions as will make it include more flux; Maxwell (Art. 489 and 490) states

it in equivalent terms. It will be shown below that this law, though often true, is not based on the correct fundamental principle, the increase in flux so often noticed being an incidental and indefinite secondary consequence which may or may not take place, and is not the true primary cause, and therefore not the proper crucial factor in a law. In the most usual case of a motor, the flux does not increase but remains constant, hence the law fails even in the most usual case; complicated and involved definitions of sliding contacts must be called to the rescue; the Faraday unipolar motor eliminates the element of commutation. But more than that, in the simplest and most fundamental case, which is described below, (the proof of which is given in the Appendix) the flux is actually *less* in amount after the motion.

This law has led many to draw wrong conclusions, as was illustrated by the writer receiving from many physicists a positive answer to a certain case which was directly contrary to the facts. Moreover it is the flux energy and not the flux which is concerned when a circuit does work in producing motion; the flux energy may increase or diminish while the flux can remain constant.

Another favorite law is that only such motions will take place as will increase the self inductance. This is a badly defined law as it involves a factor which is entirely foreign to the case, the number of turns in a coil; the magnetic forces are entirely independent of this factor, at least for direct currents; they depend on the ampere-turns. The self inductance is a purely geometric quantity and is independent of any current or energy. In every motor, and in certain electric furnaces in which powerful motion exists, the self inductance remains constant, as also in the experiment Fig. 17 described below. In the one described in Fig. 16 it will be generally admitted that it actually is *less* after the self produced motion. Another case in which it is less after the motion is referred to in the Appendix. It may be claimed that these cases are unusual ones; but a law to be depended upon as being really universal must not have a single exception. The magnetic energy stored in a coil depends only on the ampere-turns, the reluctance and the flux, it is entirely independent of the self inductance in the sense that the latter may be greater or less in different cases in which the former are the same. The fact that this energy is readily calculated from the self inductance of any particular coil and the current, misleads one to believe it to be a crucial factor in matters concerning energy, but it is not, as the energy is dependent on the ampere-turns but not on the turns by themselves.

Another law is to the effect that anything that increases the stored energy will give rise to a force. There is no such increase in a running motor; and in the most fundamental case described below the stored energy becomes *less* (as it should) when the force acts.

Another is that such motions will take place as will

increase the permeance. This also fails for motors unless rescued by forced definitions of sliding contacts. A noted physicist recently explained to the writer that in a certain experiment the motion was due to an "increased reluctance" the exact reverse of an increase in permeance.

With such ambiguities and inaccuracies of the older laws, a new law seems very desirable. Above all a law should not forbid what may be possible.

A GENERAL LAW OF MOTIONS

In view of these discrepancies, and the fact that when forces act to produce motion it involves energy, the writer concluded to look for a general, universal law among those for energy.

There is a well recognized general law in physics applied generally to a system of mechanical forces and energy, to the effect that *in any system such motions will tend to take place as will reduce the potential energy of the system*; this potential energy is thereby transformed into the kinetic energy of the motion; water flowing from an elevated storage reservoir is a simple example.

It is believed that this is a universal law of nature and therefore should apply in quite as general a way to any and all electromagnetic systems in which potential energies are involved and mechanical motions are produced. To make it more convenient to be applied directly to electromagnetic systems, it seems preferable to redraft it and state it in such electrical terms that it will not only be correct and easily understood but that it cannot be misunderstood, nor will deny what may be possible. What the best wording is, is a matter of opinion.

The writer suggests the following version for the usual conditions: *in an electromagnetic system in which the current is being maintained by a source, any and only such mechanical motions of the conductor will tend to take place as will generate a counter e. m. f. somewhere in the circuit*. The actual motions which this tendency will produce will depend, of course, on the particular freedom of motion which the various parts of the circuit may have. The counter e. m. f. is not necessarily generated in the part that moves as will be shown below. It is believed that this is a universal law of all such electromagnetic systems, that is, that there are no exceptions.

The reason for introducing the clause about the current and the source is to exclude certain very unusual cases, like condenser discharges, and others in which there is (as with permanent magnets) no outside source of supply of additional energy when some is withdrawn from the system; to also include such unusual cases the statement of the law would seem to have to suffer in simplicity. The universality of the law is, of course, claimed only for the cases specified in it, which however are the usual ones.

Magnetic material such as iron in such a system can

store and give off some energy and thereby may introduce a correction factor in some cases. General laws are supposed to be exactly correct only under theoretically perfect condition, and just as the element of friction does not invalidate the general laws of mechanics, so the presence of iron should not be considered as invalidating this law.

It will be noticed that, as in the general law, there are no further restrictions as to any particular directions of the forces which cause these motions; nor are there any apparent reasons why there should be; according to this version of it any and all motions whatsoever are therefore justified, no matter what the direction of the forces may be which cause them.

The chief reason for proposing this electrical version of the general law is that it is believed to be without exception and in fact a necessary consequence, that when any current-carrying system which is connected to a source produces mechanical motions of any kind, that is, gives off energy, there is always produced a counter e. m. f., which when multiplied by the current (in phase) is the quantitative equivalent of the mechanical energy produced. This alone might justify this version, but there are further reasons and explanations.

THE COUNTER E. M. F.

In a system consisting of current-carrying conductors, it will doubtless be conceded that at least in the sense of this general law, the potential energy in an electromagnetic system resides in the magnetic flux energy which is stored when the current was started and is somewhat like that of inertia. It will probably also be conceded that any self-produced mechanical forces which tend to produce motions, are the direct results of the action of the energy stored in this flux, which may for this purpose be considered as a sort of stress or strain or inertia; the greater this flux energy the greater the forces are likely to be. It is believed to be true also that when such flux energy actually produces mechanical motion, that is, kinetic energy, it disappears as such, just as when a mechanical stress of strain relieves itself by producing motion it disappears as such; but such a disappearance is quite different in kind from that occurring when a current-carrying circuit is broken, as the potential energy of the flux in the latter case is transformed into energy in the form of the momentary current caused by the direct e. m. f. which the disappearing flux produces; the e. m. f. then is a direct and not a counter one.

When the potential energy of the flux is transformed into the kinetic energy of mechanical motion, it seems evident that no counter e. m. f. should be produced directly thereby, though there will be when this lost energy is subsequently replaced again by the current. This is shown by the following example of a more fundamental case.

Assume two parallel copper rings at 0 deg. absolute temperature at which their resistance is zero; let like

and equal currents be started in both by drawing a magnet pole through them; the energy of this process will then be stored as magnetic energy and the currents which maintain it would then continue to flow indefinitely. Now let the rings move toward each other by their attraction over a certain distance and then stop, thereby converting part of their potential energy into kinetic; there will then be less magnetic energy and therefore less current flowing after the motion has ceased; this cannot be due to a counter e. m. f. as the motion has ceased.

If two unlike poles of two permanent magnets are permitted to move toward each other, an amount of the flux energy must have disappeared exactly equal in amount to the kinetic energy produced by this motion; this is restored again when the two poles are subsequently forced apart.

In both of these cases the flux itself as distinguished from the flux energy, will also be found to be less, the proofs of which by Prof. R. E. Brown are given in the Appendix.

These two illustrations were chosen because there is no source of new energy connected to them to replace that which was transformed into mechanical energy. They are therefore more basic or more fundamental than the usual cases, as showing what actually takes place physically in the simplest case, and the order in which things take place; they both show that when the potential energy of the flux is converted into the kinetic energy of motion the flux energy (and in fact the flux also) disappears as such, and in the former case without generating any counter e. m. f.; the process here is not masked by any addition of energy from an outside source. The immediate, practically simultaneous, replacing of this lost flux energy by the usual source is therefore hereby shown to be a secondary consequence, and not the primary cause of the motion, and it is this supply of new energy which really generates the counter e. m. f., just as in the starting or increase of a current. This seems to be an explanation of the reasons why a counter e. m. f. is always generated when such a system generates mechanical motions.

Concerning the above proposed experiment with the two rings at absolute zero (the result of which can be definitely calculated, as shown in the Appendix, easier than it could be measured), it has been variously claimed by some that with zero resistance it is not possible to induce any current at all, and by others that even with the slightest induced e. m. f. the current would then be infinite; these are rather large differences of opinions. The facts are that at nearly 0 deg. Onnes induced a finite and limited current which persisted for a long time. For the purpose of the above argument it may be assumed that the conditions are like those in the Onnes experiment, therefore possible, and that the current was not decreased appreciably by the very small resistance, during the very short time of the motion.

That the current would not be infinite at absolute zero resistance nor enormous near to zero, is shown by the fact that the finite amount of energy spent in drawing the pole through the rings, is stored in the system as magnetic energy of an exactly equal amount; it could not possibly be any greater. Hence the current which would flow continuously is only that which by its ampere-turns and with the existing reluctance, would produce and maintain exactly that amount of flux energy. It is analogous to the energy of inertia stored in a spinning top, under frictionless conditions.

THE POTENTIAL ENERGY

One of the objections to using the term "potential energy" in the above electrical equivalent of the general physical law, is that it may not always be clearly and definitely understood. But a greater objection is that it may sometimes involve necessary and perhaps complicated explanations of apparent contradictions and ambiguities; the diminution and disappearance of the potential energy (the energy in the flux) is not always as readily apparent as it is in mechanics; especially as the process is generally masked by an immediate replacement of this energy by the source; in a motor the ultimate quantity of the flux energy remains constant; in some cases it is even greater after the motion than before. There is a generally accepted law (though as shown above it is not always correct) that a circuit always tends to move so as to embrace the largest possible amount of flux, therefore apparently directly contradicting this general law; the amount of the flux and of the flux energy however, by no means necessarily vary in the same ratio, the energy is the product, of the flux and the m. m. f.

A careful and unbiased analysis will, however, show that these contradictions and anomalies are only apparent and not real; it can be shown that any additional or new flux energy has in those cases been added by the source of current after the motion has taken place or while it is taking place; the motion itself may have made room for more flux or have decreased the reluctance. This increase of flux energy is a secondary result and not the primary cause of the motion, as seems to have been claimed; it may or may not take place. Similar anomalies and apparent contradictions occur in the application of the more general law to purely mechanical conditions, yet they do not in fact violate that law; for instance, the potential energy in the water in an elevated tank which is being kept full by a pump, will according to the general law, cause it to flow into and fill another neighboring tank and at the end of the operation there will be more potential energy than there was at the start. To avoid such anomalies and apparent contradictions it seems preferable to use a different term than potential energy in the electrical equivalent of this general law.

Maxwell (Art. 568) defines potential energy as a tendency to a change of relative position, and he some-

times treats the energy of magnetization as potential. He says furthermore (Art. 638) that he "assumed that the energy of a magnetic system is potential energy, and that this energy is *diminished* when the parts of the system yield to the magnetic forces which act on them." (The Italics are his).

To the writer it therefore seems that the generation of a counter e. m. f. is the best crucial condition in the electrical equivalent of that general physical law, to take the place of the reduction of the potential energy. That they are the equivalents of each other, or at least necessary accompaniments of each other, when there is a source, seems evident; the general physical law calls for such motions as will reduce the potential energy, the flux energy in the electrical case; this flux energy then must disappear as such when it is transformed into the kinetic energy of motion; as the current necessarily always generates as much flux as the reluctance of the surrounding space permits, it will at once replace any flux which has thus disappeared and, as is well known, the generation of any flux in a circuit is always accompanied by a counter e. m. f. The writer has applied this simple law to every case he could think of, old and new, and it never fails to apply correctly. If no exceptions can be found to it then it seems to be a universal law for the class of phenomena specified in it.

The Hall effect, like the skin effect, seems to deal with the shifting of the current paths in a conductor, as distinguished from a movement of the conductor itself. They therefore would have no direct bearing on this law except in so far as the changes of current paths may change the flux distribution which in turn may affect the forces.

DEDUCTIONS FROM THIS LAW

If this law is sustained, a number of deductions follow. It specifies no limitations to any particular directions of the forces which produce the motions, hence any directions are possible, provided only that the motion generates a counter e. m. f. somewhere in the circuit. It has been strenuously maintained that these forces could be only perpendicular to the conductor and never otherwise; it therefore opens up a formerly forbidden field. If for instance any particular motion is desired, it follows from this law that if that motion is such as would produce a counter e. m. f. then it ought to be possible to make the system produce it by providing the necessary freedom of motion; this has for instance been made good use of for giving molten metals a desired motion in some types of electrical furnaces.

Lengthening a current-carrying conductor (the stretch effect), reducing its cross section (the pinch effect), straightening it (the corner effect), winding it into a coil, etc., all produce a counter e. m. f. in a constant-current circuit and the circuit could therefore (theoretically at least) be made to produce them. According to Lenz' Law reversing any of these motions should generate current. Some of these deductions are further discussed below.

LONGITUDINAL FORCE

One of the deductions from this law is of special interest because it has been most hotly contested; there is however also another proof of this deduction which is entirely independent of this law (and therefore aids in confirming the law) as will be shown in connection with Fig. 9. If a current-carrying conductor be lengthened (as for instance by stretching, sliding contacts, mercury troughs, etc.) new flux will be produced around the added part and the production of this will generate a counter e. m. f., as in any conductor in which a current is started. Hence it would follow from this law that the circuit itself could produce such a lengthening if the necessary freedom of motion exists. In other words, a current tends to stretch or lengthen its conductor, or more generally, there are longitudinal forces tending to move the conductor in the direction of its axis.

This force, the existence of which can readily be shown experimentally as described below, the writer years ago colloquially termed the "stretch effect," it being a complementary phenomenon to the "pinch effect" which tends to crush the conductor radially, both seem to follow the same laws and lead to the same ultimate result in liquid conductors by rupturing them, when strong enough.

This longitudinal force is also a consequence of conceiving that these electromagnetic forces have their real origin and abutments in the material of the conductor at the seat of the moving electron which causes them; that is, the forces in the field around a conductor are actions at a distance (as Faraday maintained). In Fig. 1 the lines *m m* represent the disks of flux around those parts of a conductor; such like lines of force are known to repel each other, and if the seats or abutments of these repelling forces are in the material of the conductor where the electrons *e, e*, which produce these lines are moving, the conductor will tend to stretch. The greater the density of this self repelling flux the greater this force.

Physicists have emphatically denied and many of them do so still, that such a longitudinal force exists or could exist.² Maxwell (Art. 507) described an experiment, due to Ampere, made under certain conditions, from which he generalized that no such force existed or could exist; the writer admits that it would not make its appearance under the conditions in that particular test, (in which the two longitudinal forces are equal and opposite), but that under different conditions to be described below, (Figs. 3 to 11), this force becomes very evident. Recognizing both forces means that a resultant in *any* direction is then possible.

This longitudinal force does not appear in the usual mathematical treatments of electromagnetic forces; the reason seems to be that such treatments were originally

2. Northrup's Laws of Physical Science (1917), p. 152, par. 3. "If a wire carries a current no external magnetic force can so act upon the wire as to tend to make it move in the direction of its length."

based on a special case in which this longitudinal component consists of two opposite forces which are exactly equal and therefore drop out of the mathematics; having once dropped out this force can of course never again reappear in any subsequent mathematical deductions which are based on this original case even when they are unequal, as they are in some of the experiments described below.

These two new forces, the pinch effect and the stretch effect, are generally not great enough to crush or stretch solid conductors, (though they might perhaps act on the softened filaments of forced incandescent lamps), but with liquid or gaseous conductors like those in some electric furnaces or in the arc, they may become of vital importance, being sometimes quite formidable, and should therefore be recognized, studied, and included in mathematical treatments; to deny their existence might check possible progress and developments. That they are of practical importance is shown by the fact that hundreds of electrical furnaces are at present in daily successful use in which this longitudinal movement of the liquid conductor by its own current, is the absolutely essential factor.

Some physicists who declined to recognize this longitudinal force have endeavored to explain the very evident longitudinal movement in the writer's earlier experiments with liquids, as a hydrodynamic action of the liquid due to the pinch effect. But as some of the experiments described below show that this force will also move solid conductors lengthwise, they are a positive proof that the action cannot be primarily hydrodynamic in the liquid; in the writer's opinion the hydrodynamic action resides in the field itself.

Unlike the stretching of a compressed helical spring, this stretching theoretically continues indefinitely and is constant if the current and the cross section of the conductor remain constant, as in a mercury trough. As in all these phenomena, it will no doubt be found to increase as the square of the current. It is independent of the direction of the current or the length of the conductor. For the same current it becomes greater the smaller the cross section and can rupture the circuit by tearing it. It no doubt is greatest at the center of a round conductor and is least at the circumference. In a liquid conductor the motion is therefore greater along the central axis than near the circumference. Like a compressed helical spring a flexible circuit secured only at the two ends may form itself into the shape of the letter *C* as is often seen in the arc, or even like the letter *S*, if thereby it can lengthen itself (see Fig. 8). It has been suggested by a noted physicist that this might explain the sinuous character of a bolt of lightning.

A circuit making an angle at a hinged joint tends to straighten itself, due to this stretching force. This is usually explained by the action of the component of a force perpendicular to the moving part, and when it is straight this force which straightened it becomes zero. It can be shown however, that if the necessary freedom

of motion exists at the joint the force which straightened it, namely the repulsion of the disks of flux, still continues and will then stretch it, showing the older explanations to have been wrong. A flexible circuit is known to expand; why should this same force cease when the conductor becomes a straight line; it does not; our former limitation to a perpendicular force has misled us. A straight soap bubble film (therefore having no radial pressure) has a tension just as the curved one has.

A straight conductor leading down into a large liquid conductor tends to be moved upward out of the liquid, if the proper freedom of motion exists, and new flux will appear around the lengthened part, causing the counter e. m. f. In general, where there exists any difference of flux density near a conductor there will be a tendency to produce a motion to equalize this flux density if that motion would generate a counter e. m. f. In experiments care must of course be taken that the force is not counterbalanced by an equal and opposite force somewhere else, which is generally the case. As will be shown below, the longitudinal force may be made very evident by making the two opposing forces unequal.

Ampere had referred to such a possible longitudinal force and gave some formulas; this is briefly discussed by Maxwell (Art. 526) and is not then denied by him, though he denies it elsewhere. In Art. 687 however he described the Ampere trough experiment (see Fig. 5) saying "This experiment is sometimes adduced to prove that two elements in the same straight line repel one another" (this is what the present writer calls the stretch effect) "and thus to show that Ampere's formula, which indicates such a repulsion of collinear elements, is more correct than that of Grassman, which gives no action between two elements in the same straight line." Maxwell adds that the experiment does not favor one more than the other; it is significant that he here does not deny such longitudinal forces, though he does elsewhere.

According to Maxwell (Art. 527) Ampere had claimed that the force between two elements of the circuit, (evidently meaning limited parts of a circuit, or of circuits), is along the line joining them, which Maxwell (Art. 527) considers the best assumption. For conductors inclined to each other, such lines joining their parts must necessarily be inclined to them, hence such forces *must* have longitudinal components. (See Fig. 9).

THE CORNER EFFECT

Many years ago the writer noticed that in a wide mercury trough which turned a right angled corner, there was great agitation of the mercury at that corner when a large current flowed, showing the presence of decided local forces; the current was not great enough to show a marked pinch effect in the straight parts; he called it the "corner effect." The writer's explanation was that as the amount of flux must of course be the same on the inside and outside of the corner, the density must be far greater on the inside part of the corner,

therefore the forces on the mercury there must be far greater than those on the outside part, hence the agitation.

Recognizing the existence of the longitudinal force, this experiment can also be described as the mutual action of two currents whose conductors are inclined toward each other (see Fig. 9); the forces will of course be greatest where they are nearest to each other, in this case at the corner. When these two currents are unlike in direction (as in the above case) there should be a longitudinal flow of the conductor away from the corner, and for like currents toward the corner. An electric furnace based on this, for obtaining a unidirectional flow of the liquid conductor, operated as predicted, the motion being quite strong and rapid (*Jour. Frank. Inst.* Nov. 1921, Fig. 9 and p. 612).

QUANTITATIVE VALUE OF THE PINCH EFFECT

In the c. g. s. system the writer found (*Met. & Chem. Eng.* Vol. 9, Feb. 1911, p. 86) that the quantitative value of the pinch effect at the central axis of a circular conductor was $P = I^2/S$ in which P is the pressure in dynes per square centimeter, I the current in c. g. s. units, and S the cross section in square centimeters. This pressure is of course greatest at the center and least at the circumference. The fact that this is a unit relation in the c. g. s. system is of interest. It will be seen that the pressure is not proportional to the current density. As the current in a given liquid conductor is increased, an unstable state is ultimately reached at which this force increases automatically by contracting the conductor enough to rupture the circuit.

HYDRODYNAMIC ACTION IN A MAGNETIC FIELD

No one has yet deduced the quantitative formula for the longitudinal force, this force having dropped out of our present mathematical treatment of such forces. But the writer has reasons to believe it will ultimately be shown that these electromagnetic forces in a magnetic field act as though the medium, the ether, were like a liquid or gas, that is, they act hydrodynamically and therefore can turn corners, as it were. As they act on solid conductors also, the conductor itself need not be this hydraulic medium, as was formerly claimed by others.

If this is true, the quantitative formula for the stretching should be exactly the same as that for the pinch effect. Some years ago Northrup made a very careful and accurate measurement of what he claimed was the pinch effect, but as the force he measured was a longitudinal one (claiming that the liquid conductor, mercury, acted, as the hydraulic medium) the writer maintains that what he really measured was this stretching force. His measurements confirmed the formula of the pinch effect, hence the writer's conclusion that they are numerically equal. Maxwell (Art. 109) in discussing so-called static electricity says "the numerical magnitude of the pressure" (between lines of force of static electricity) "being equal to that of the tension" (along these lines) "and both varying as the

square of the resultant force at the point." Many parallels between electrostatic and electrodynamic phenomena exist.

If these forces act as though the medium (not necessarily the conductor) were a fluid, the whole subject is simplified as only one of the two magnetic forces need then be recognized as the primary, either and preferably the tension along a line of force, the other, the repulsion of like lines, being a hydrodynamic resultant, just as the radial pressure on the side of a cylindrical pump is produced by and is exactly equal to the longitudinal pressure of the piston.

POLE MOVING ALONG A LINE

A third electromagnetic force is sometimes included with these two, namely the force which tends to move a single pole along a line of force; Faraday showed this in a very ingenious experiment (see Fig. 12). This force is however not a property of the field itself, but of a foreign body which is introduced into it, that is, the force is that between two independent fields.

There is a deduction from this experiment which seems to bear out one of the writer's contentions. It will be conceded that when a single pole moves along a line of force encircling a conductor, the equal and opposite reaction required by Newton's third law should tend to rotate the conductor around its axis in the opposite direction, which it does, as will be shown below. As there is no physical connection between the pole and the conductor it seems that the flux around a conductor must be considered as though mechanically connected with its conductor, or in other words that it is a case of action at a distance from the moving electron.

THE "SLIDING CONTACT"

The most unsatisfactory and most confusing element in our present system, and the most troublesome and discouraging one to the student, is the inevitable "sliding contact." Every book-writer and teacher seems to try to invent a new definition.³ When new

3. As a good illustration the following is from a letter recently received from a professor of physics in a well known college, who is responsible for teaching many young men. "I think the only satisfactory way to treat such cases, and the way in which they usually have been tacitly reasoned out, is to imagine the sliding contact replaced by a very thin layer of conducting liquid in which the motion varies continuously from one surface of the layer to the other. Then everything becomes clear (!). . . Sliding contacts are to be treated as the limiting cases of a thin transition layer in which the motion varies continuously from one side of the layer to the other." He speaks of "what happens to the flux-linkage when the filament is broken by the sliding at a sliding contact. . . If you do not like my conducting fluid (in the above definition), then put in a short wire across the break and consider what happens during the thousandths of a second before the wire breaks." The circuit was never broken in the case referred to.

A well-known electrical engineer and able physicist defined a sliding contact as a "commutator with an infinite number of sections." Maxwell (Art. 491) says that in the case of a sliding contact the circuit "must be regarded as a system of two or of some greater number of circuits of variable strength," currents of even opposite directions.

experiments conflict with the older laws, a new definition is at once invented to try to make them fit, and this seems to be quite satisfactory to many physicists. To the writer however the responsibility placed on the sliding contact has always appeared as a tacit admission that something is wrong, an admission of our ignorance or of some mistake.

All this could be avoided by the revision suggested below. The adequate definition of a sliding contact then reduces itself as it should, merely to "a contact which slides," and nothing more.

GENERAL LAW OF INDUCTION

Our laws of induction (Faraday's law of cutting lines of force and Maxwell's law of change of linkages in a complete circuit) were based on special cases. They have been invaluable and perfectly satisfactory when limited to those special cases. But trouble and misfits generally arise when the laws for one special case are applied to another special case; it is unwise to attempt it. Moreover as both are special cases can we depend upon it that together they cover all possible cases, without exception, that is, are they universal.⁴ Has not our belief that they are universal perhaps checked development in other special cases. A single pole will move around a conductor, hence the reverse motion should generate a current. A magnet will rotate a conductor (Fig. 14) hence rotating the conductor near a magnet should generate a current. Contracting a current-carrying conductor, or expanding its cross section, or unwinding it from a coil, and perhaps many other odd motions, ought to generate current. Some of these cases of induction are difficult to explain by our present laws, except perhaps by means of special forced and involved definitions of a sliding contact. Our older laws would surely not have led us to them, though no claim is made here that those above mentioned are of any industrial importance.

The writer maintains that this state of affairs is not satisfactory and that we ought to look for a more fundamental general law of induction, of which the present ones are then special cases, to which they should then be limited. Such a general and presumably universal law could be based on a combination of the new law given above for motions and Lenz' law, that is, if any of these self produced motions are reversed, there will be induction. Lenz' law has presumably never been questioned, and the law of motion is nothing more than an electrical version of a well established and non-contested law of physics concerning energy; both are believed to be universal. In such devices as transformers the relativity principle is then also involved, in that it is immaterial whether the conductor moves across the flux or the flux (originating with the moving electron) moves across the conductor; there is relative motion in either case.

4. That Maxwell considered his law to be universal is indicated in Art. 541 in which he says we can "enunciate completely the true law of magneto-electric induction" in this way.

INTENSITY AND DIRECTION OF FIELD NOT SPECIFIC ENOUGH

It has been claimed that a magnetic field is completely specified by its intensity and direction. This means that if the source, either a magnet or a current-carrying conductor, moves in such a way that the field at any outside point does not alter its intensity or direction, then the field does not move, in the sense that it would not cause induction in a fixed conductor. Experiments seem to indicate that each line is attached to its source, the conductor, as the rim of a wheel is attached to its hub, except that the attachment is elastic. If so, the above definition of a field is incomplete and should include a reference to the motion of the source, even if such motion does not alter the intensity or direction at any specific point. See also Figs. 15 and 17.

PRESENT MATHEMATICAL TREATMENT NEEDS REVISION

Our usual mathematical treatment has misled us in creating a very positive and nearly universally accepted belief that the only force which can possibly exist is one perpendicular to the conductor, like the one in the definition of the unit of current. This has checked progress. The usual mathematical treatment should not have been based on a special case in which the longitudinal force happens to fall out in the mathematics.

A new mathematical treatment should now be devised in which the longitudinal force is recognized. The mathematical short cut based on integrating around the "complete circuit" which often involves quite unnecessary complications, should be limited to those many cases in which it is useful. It should be accompanied by a mathematical treatment (far more difficult to devise) based on limited parts or elements of circuits (as proposed by Ampere) and on their relative inclination and distance apart. When a desired force is like that between two inclined conductors, by far the greatest part is where they are nearest together, and we should therefore be able to determine how long it is economical to make such conductors.

It is believed that such a system could be based on the assumption of only a single magnetic force, the tension along a line of force; then deduce the other, the repulsion of like lines, on the basis that there is an action analogous to that in hydrodynamics and that therefore this one force can produce motions in *any* other direction depending only on the freedom of motion which exists. It should also be based on the forces being actions at a distance, the abutments of these forces being in the material of the conductors and in that part in which the corresponding electron is moving.

EXPERIMENTS

The following experiments, mostly original with the writer, illustrate some of the facts, opinions and departures expressed above. The results in many of them were in accordance with the predictions based on

these opinions and contrary to opinions based on the older laws. Gospel faith in the older laws would not have led to them. Some of them have been published before and are reproduced here (by request) to illustrate the deductions from them. Many of them have been discussed for some time with able physicists whose comments have been considered, though generally when they could not justify them with the older laws they ignored the experiments.

The apparatus was mostly crude and improvised though the results were always quite definite and decided. No claim is made that this is a thorough and completed research, nor were any quantitative measurements made. The experiments should be considered merely as a preliminary investigation.

As it is often not possible to multiply these forces by using coils of many turns, the currents required are generally rather large and cannot be kept flowing long on account of the heat. About six storage batteries of the usual portable laboratory type, and a low volt transformer giving up to about 2000 amperes, were generally used; in some cases a dry cell current suffices.

In Fig. 3, W is a long horizontal wire suspended so that it can move lengthwise. One end dips into the center of a large dish of mercury O , in which, therefore, there was practically no change in the flux when the wire moved slightly. The other end dips into the narrow mercury trough M , in which a force to stretch or lengthen that electrically elastic part of the conductor could manifest itself. When current was passed the wire moved decidedly to the right showing the tendency of the part M to stretch. Assuming a constant current, new flux was produced in the part which was added to the mercury trough part of the circuit by this lengthening; and it is in this part that the counter e. m. f. must have been generated. Moderately large currents must be used unless the apparatus is light and sensitive, though they should not be large enough to cause an appreciable pinch effect in the part M . The vertical parts were made very short and can be neglected (see Fig. 6). Care must be taken to have the whole circuit in a vertical plane, or there will be a disturbing side motion of W .

Fig. 4 described over a decade ago is of interest because without exception every one of numerous physicists gave the wrong answer as to the direction of motion, showing how badly our older law had misled us. A horizontal wire W is pivoted at P , the other end being free to move in a curved mercury trough M . It was placed in the position as shown before the current was started; with current it moved in the direction shown, which is the contrary one to that called for by the older law that a circuit tends to expand. The enclosure of the circuit *decreased* instead of increasing. The writer's explanation is that the only part of the circuit which has a freedom of motion to lengthen itself, namely the mercury part, did so. When started on the other side of the "dead point" it of course moved in the opposite direction, for the same reason.

Fig. 5 is a modified form of the classical Ampere trough experiment. B is a bridge wire floating on the two mercury troughs $M M$. In the original experiments by Ampere the battery circuit was placed at the left as shown in dotted lines, and the resulting movement of the wire B to the right was attributed to the old law that the circuit tends to enlarge itself; also to the repulsion due to that part of the battery wire which is parallel to the bridge wire. The writer attributes the motion to the tendency of the mercury parts of the circuit to lengthen, owing to the lateral pressures of the disks of flux around them; they are the only parts in which this force is free to act. This was shown to be the correct explanation, and the older explanations were shown to be wrong, by reversing the position of the battery cir-

cuit as shown in full lines, as the motion was then in the *same* direction, as it should be, while according to both the older laws it should have been reversed. The battery wires should not be too near the troughs.

It is of interest that Ampere himself thought there was some such longitudinal force in this experiment, but his followers, notably Maxwell, were not convinced; it did not fit in with Maxwell's mathematics.

An interesting feature about this experiment is that, assuming a constant current, the counter e. m. f. is evidently generated in the parts which are added to the lengths of the trough part of the circuit, as these are the only parts around which new flux has been generated, hence it is not essential that the counter e. m. f. must be generated in the part which moves, namely B ; a motion may therefore be produced if a counter e. m. f. is thereby generated in *any* part of the circuit. While B is the part which moves, the forces which move it reside

entirely in the mercury trough parts, and not in B itself, as is generally claimed.

In Fig. 6, a long horizontal wire W suspended so that it has freedom of motion lengthwise, has one end dipping into a mercury trough M the cross section of which is large, and the other end into one (m) in which it is small. For the same current the flux encircling the large cross section in M is of course less in amount than that around m hence the lateral repulsion of this flux in m should be greater than that in M ; the wire W should therefore move to the right, which it does quite decidedly.

It was, of course, claimed by the upholders of the old law that this was due to the repulsion of the vertical parts entering the troughs, even though they had been made very short. These were therefore placed as shown, close together in M and far apart in m , yet the movement was still in the same direction though slightly less in intensity; it should have been reversed if caused by those vertical parts. This shows conclusively that the movement was not due to these vertical parts and that the longitudinal forces were greater as they overpowered the others.

Fig. 7 shows a better and simpler way of making the same experiment. Three long slender mercury troughs were made as close together as possible, the walls between them being made as thin as possible. A movable copper bridge piece B floating freely on the mercury, connects them. The meniscus of the mercury projected slightly above the troughs so that the bridge piece had practically no vertical component. Both of the right-angular parts of the bridge piece were therefore made so short that they could be neglected; this was done because it is these right angular parts that the upholders of the older theory depend upon; the previous experiment in Fig. 6, however, in which these perpendicular parts were much longer showed conclusively that even when very much longer than in Fig. 7, they did not determine the motion.

When current was passed into the middle trough and out of the outer two (or all three) the bridge piece moved very decidedly and quite rapidly to the right. The motion appeared to have a constant velocity. The explanation is the same as in Fig. 6, that the flux around the smaller cross section was much greater than around the larger one, hence the longitudinal force of the former overpowered that of the latter. This apparatus is in a more convenient form for a lecture room experiment.

In Fig. 8, a well amalgamated copper chain was laid in a much longer mercury trough in a contracted position so that it could stretch. When the current was passed it immediately and decidedly stretched to its extreme length. Copper being a far better conductor than mercury most of the current passed through the copper, which having a far smaller cross section had much more flux around it than there was around the ends of the mercury trough, hence the longitudinal force overpowered that at the ends. As the copper is likely

to be sucked under by the pinch effect (where the stretch effect is also stronger) and disappear while the current is flowing, it is well to float the ends with some light non-conductor.

This experiment also meets the claims sometimes made that in some of the movements in these experiments it is the pinch effect which by its hydrodynamic action in the mercury causes the motion. If the pinch effect were the cause, it would act to push the ends of the chain towards the middle, but the fact is that the movement is in the *opposite* direction. This experiment which requires large currents, might perhaps be more conveniently carried out with much smaller currents by suspending the chain from floats in an electrolyte.

When this chain was laid in a contracted form in circular mercury dishes C and S with its ends secured near the terminals, and in the positions shown by dotted lines, it stretched itself into the positions shown in full lines when current was passed, as a compressed helical spring would do. Repeated short applications of the current seemed to act better.

Fig. 9 is a modified form of an old experiment attributed to Faraday or perhaps to Ampere. It furnishes a different and independent proof of the longitudinal force and one which it is difficult if at all possible to meet by the older laws. In the original a vertical conductor V was mounted so that it could move to the right or left parallel to itself. It contacted with a horizontal wire H which was stationary. When currents were passed in the directions indicated the movable wire V moved to the left.

The writer maintains that as the movement of V was caused by the current in H , then if the apparatus be reversed so that V is fixed and H has a freedom of motion in the opposite direction, the same force would move H in the direction of its length, which it did, thus showing the existence of this strongly denied longitudinal force. This must follow from Newton's third law, that for every action there is an equal and opposite reaction. It also must follow from the view of Ampere and others, apparently endorsed by Maxwell (Art. 527), at least not denied by him, that the force between two elements is along the line which joins them, as shown by the diagonal line. If so, such a direction must have components in the directions of the lengths of both conductors.

It seems strange that although this experiment, the law of Newton, and the views of Ampere, have been known for the past hundred years, this method of proving the existence of the longitudinal force has apparently not been considered before, or if it has it has certainly not been generally known, or had been forgotten, and is still being strongly contested.

In the writer's modification the wire V was fixed and the long wire H was suspended so that it had a freedom of motion lengthwise. When the currents were passed in the directions shown, the wire H moved to the right, or when one of the currents was reversed, then to the

left. The contact between the two was made with a small mercury trough carried by H . When H was fixed and V allowed (by means of a mercury trough) to move in the direction of its length, it so moved away from H . Before the experiment a current was passed through H alone to make sure that no motion was caused by the very short vertical parts that dip into the mercury dishes; moreover the final motion was again in the opposite direction to what it would be if it had been caused by these vertical parts as most physicists will claim, because the current in one pair of ends is necessarily greater than in the other.

It will probably not be denied that the forces involved are concentrated almost entirely at or near the corner where the conductors are nearest together; it is therefore a weak argument to make a crucial point, as has been done, of where the "rest of the circuit" is. Beyond a few inches from the corner the circuits have probably an entirely negligible effect on the forces, and it therefore does not matter where they are. Some physicists have "grabbed at straws" to uphold the older laws, instead of being helpful in trying to improve them.

This same test was also made and exhibited by the writer some years ago, in a different way, resembling more closely the apparatus existing in many physical laboratories to show the original experiment of Faraday. H was a stationary circle and V moved around this circle. In the modified form V was fixed and the circular part moved. Sliding contacts were used to replace the usual liquid conductor and this caused much friction, but still the movement was quite decided, and was witnessed by many.

In Fig. 10 three short pieces of well amalgamated copper wire were floated on a mercury trough in a straight line with their ends close together. When alternating current was passed they separated a short distance as shown, but would move no farther even with repeated applications of the current. This seemed to indicate that the denser field around the copper pieces was, as it were, elastically connected to its conductor and that the repulsion of like lines made it extend itself a slight distance beyond the ends.

Fig. 11 shows an interesting difference between a direct and an alternating current. A kite shaped piece of well amalgamated copper was floated as shown on a circular dish of mercury. The idea was that the denser flux around the main path near the small end would produce a greater longitudinal force than the less dense flux around the much larger main path at the larger end, thus causing the piece to move to the right. With direct current it moved every time the circuit was closed but only for a very short distance and then stopped. An alternating current ought therefore to move it continuously, which it did, across the whole bath and at apparently a constant velocity, always in the direction of the large end forward. This experiment showed that the motion was not due to the pinch effect, as had been claimed, though if the current be-

comes very great the alleged hydrodynamic resultant of the pinch effect in the liquid conductor will contribute to the motion.

Fig. 12 represents Faraday's ingenious experiment to show that a single pole N of a magnet moves along the circular lines of force around a fixed current-carrying conductor C . This experiment does not seem to be described in his well known *Experimental Researches*, but was published by him in the *Quart. Jour. of Sciences*, XII, 186, and again with an illustration in the next issue 283; the date seems to be about 1822, just 100 years ago; this description is included in a later collection of his works. Maxwell (Art. 486) refers to Faraday's experiments and shows a figure (Art. 491) which however is totally different from the original and the explanation accompanying it is difficult if at all possible to understand, owing apparently to Maxwell's efforts to include an involved explanation of a sliding contact, necessitated by his mathematical treatment. Faraday's own explanation is very simple and is not burdened with any such complications. The writer could find no illustration in Faraday's works corresponding to the one given by Maxwell.

In Faraday's original experiment a permanent magnet $N S$ was floated in a cup of mercury in a slanting position as shown in Fig. 12, with one pole tied with a string to the center of the dish at the bottom. The current entered through the central fixed conductor C and left through the center of the bottom. When current flowed the free pole moved in a circle around the wire C .

The writer repeated the experiment, and found that apparently the chief force was a couple, as shown in Fig. 13, which represents a top view of the upper part of Fig. 12; the conductor C and magnet pole N each endeavored to revolve around the other, as Faraday showed. If linked together and pivoted at O they should therefore revolve around O ; if the link is pivoted at P they should revolve less forcibly around P , due to the difference between the two torques; these were not tried.

When the conductor is revolvably mounted on its axis it ought to revolve when the magnet is stationary, according to Newton's third law. The revolving force is then tangential, like the pull on a string wound around the wire, and its effect therefore becomes very small when the diameter is small. By making its diameter large relatively to the distance to the magnet, especially when it is made hollow, the writer obtained decided rotation.

It is of interest that according to Lenz' law when any of these motions are reversed by an external force, a current should be generated.

A result of some interest is that when this experiment is arranged as shown in Fig. 14 in which a large (preferably hollow) fixed conductor $C C$ has a part a mounted so that it can revolve on its axis, ($b b$ being sliding contacts like a layer of mercury), it revolves when the magnet is placed as shown, parallel to the conductor.

If the magnet were mounted so that it could move around the conductor keeping parallel to itself, it would seem to have to follow that when the part a is forced to rotate there would be some movement of the magnet; this was not tried.

Another deduction is shown in Fig. 15. We are told that for the same current in the small conductor c and in the large hollow one C the magnetic effect on a point P is the same, being the same as though the current were all concentrated at the axis. Yet, as shown above, if a magnet pole be placed at the point P , it will easily rotate C , but c only with great difficulty. And if the current was concentrated at the axis, it would take an infinite force to revolve its conductor. Hence there is some physical difference between the fields around those two conductors and our older law leads us away from rather than toward this difference.

In Fig. 16, S is a solenoid mounted so that it can move down into a mercury cup M . C is a stationary coil. When like, constant, currents were passed through both, S moved downward decidedly. It thereby cuts out some of the ampere-turns, which reduces the flux generated by it; the reluctance of the combination will also be decreased somewhat but presumably in a less proportion, and if so the total flux of the combination would be *less* after the motion than before, thereby contradicting the older law that the flux increases, which it surely does not do in this case. Moreover, the self inductance is surely *less* after the motion than before; the writer had no means for measuring it. The two coils may be assumed to be in series. As actually carried out the mercury was replaced by a fixed brush, as in Fig. 17.

In Fig. 17 the conditions are similar except that the current is now led into the solenoid S by a fixed brush, B ; the other brush B at the coil was the same as before. To avoid cutting out and in a whole turn at a time, these brushes may form a complete circle around the solenoid, therefore acting like the surface of the mercury. In this arrangement the magnetic field of the combination remains exactly the same everywhere in intensity and direction, and there is no contraction of the flux as a whole, yet there was very decided motion. The self-inductance evidently also remains constant. There is no commutation. If the lines of force are not considered to be in some way attached to the moving electrons which produced them the troublesome sliding contact must again be called to the rescue to explain it. In the writer's opinion new flux is generated at the distant end of the solenoid as the current is started in new parts of the conductor, this is strongly attracted by the coil C ; the flux at the near end which is being cut out, exerts little or no attraction to C ; a part of the flux which was generated by both coils together disappears as such by being converted into the kinetic energy of the motion. The flux therefore seems to move with the coil.

Fig. 18 represents a top view of a mercury trough M

ending in two large reservoirs of mercury, to which the current connections were also made. When currents is passed the mercury in the trough should stretch thereby moving into the end reservoirs, the flux around it being far denser than around the end reservoirs. It did so, as was shown by a rapid flow of mercury from the middle reservoir R through the short connecting channel and into the trough. In this case there was absolutely no perpendicular component of the circuit on which the upholders of the older laws depend. That this motion was not due to the pinch effect, as claimed by others, is conclusively shown by the fact that if it were, the mercury in the small connecting channel should have flowed in the *opposite* direction; the action of the pinch effect would be a compression of the liquid in the trough, which would cause it to flow into all three reservoirs.

Fig. 18

GENERAL

It has been claimed that some of these experiments are "tricky" and therefore are not worthy of notice. The writer however maintains that a law to be universal must not have a single exception; if it has then possible progress in new fields is forbidden by it.

The writer desires to express his thanks to the departments of Physics and of Electrical Engineering at the University of Pennsylvania for the courtesy of extending to him the use of their laboratories for demonstrating some of the experiments. Also to Prof. R. E. Brown of Philadelphia for his encouraging cooperation in some parts of these researches. Also to the many physicists and electrical engineers whose antagonistic attitude during the past decade led the writer to a number of new and apparently significant experiments.

CONCLUSION

As a basis for discussion the writer suggests tentatively the following general outline of a proposed revision, in logical sequence, of the older laws, and of their mathematical treatment, assuming that the correctness of each step has been, or will first be, sufficiently conclusively demonstrated.

Starting with the tension along a straight line of force (the pull between magnets) as the most basic fundamental, deduce from it the repulsion of like lines and the radial force on the conductor, from the principles of hydrodynamics; then the two forces in a single conductor, the pinch effect and the stretch effect, which are independent of the length; then those between unit lengths of conductors, and those between magnets and unit lengths of conductors. Omitting the ether, recognize that the forces in a field are an action at a

distance, having their abutments in the material of the conductors or magnets, and that therefore the imaginary lines of force must be pictured as having some physical elastic connection with their source, the moving electron. Formulate in electrical terms a general law of motion (like the one suggested above) based on the long established general law in mechanics concerning the self-conversion of potential into kinetic energy. Finally on this law, combined with the Lenz law, base the general law of generators, that is of induction.

Appendix

The following is the mathematical solution by Prof. Richard E. Brown of Philadelphia, of the problem referred to above. The problem is: two like copper rings on the same axis, are reduced to 0 deg. absolute, at which their resistance is zero; like and equal currents are induced in them by drawing a magnet through them once, which currents will then continue to flow indefinitely (there is no outside source of supply); the energy put into the system is stored in the magnetic field. Let their attraction move them nearer to each other, thereby setting free kinetic energy at the expense of their potential energy; their flux energy and the currents will thereby have been reduced; (the reverse motion would increase the currents.) The question is, will the total flux of the combination have been reduced thereby.

The combined flux energy of two like coils carrying the same current, as though connected in series, is $1/2 L i^2 = 1/2 l i^2 + 1/2 l i^2 + M i^2$ in which i is the current, L the self-inductance of the combination, l that of each coil separately, and M the mutual inductance; the sign of $M i$ is plus because the fluxes are in the same direction.

The total flux linking any coil is: self-inductance multiplied by the current and divided by the number of turns; there is only one turn per coil in this case.

Assume the current carrying rings to be so far apart that there is no mutual inductance, and then to move toward each other until they coincide (theoretically), the current i being at first assumed to be maintained constant during this motion by some outside source, hence at the end there will be one coil of two turns; they are at first assumed to be filamentary, having no thickness.

When the rings are far apart (no mutual inductance):
magnetic energy = $1/2 l i^2 + 1/2 l i^2 = l i^2$

self inductance of combination = $L = 2 l$ because the energy $1/2 L i^2 = l i^2$

total flux of combination = $l i + l i = 2 l i$

When the rings coincide:

magnetic energy = $1/2 l i^2 + 1/2 l i^2 + l i^2 = 2 l i^2$

self inductance of combination = $L = 4 l$ because $1/2 L i^2 = 2 l i^2$

total flux of combination = $4/2 l i = 2 l i$.

Hence when the current is assumed to be maintained

constant, the total flux remains constant during this motion, and the magnetic energy would be doubled, being supplied from the assumed source which maintained the current constant. But in the above problem there is no such source and there must of course be less magnetic energy in the combination after the motion than before by the amount of kinetic energy given off by the self produced motion. Hence the current must have *decreased*, and as the total flux was shown above to remain the same when the current is kept constant, it follows that with a decreased current the total flux will have *decreased*.

The writer here calls attention to the fact that in the above the self inductance of the combination has been doubled by this motion, on the assumption that at the end there is one coil of two turns. The flux and flux energy, however, and therefore the forces, are quite independent of whether there are then two turns with a current i or one turn with a current $2 i$, as for instance if the rings were of mercury or of liquids in a furnace. In the latter case, the self inductance would be halved at the end of the motion instead of doubled. This shows again that the self inductance is a wrong term to use as a crucial one in such a law; also that in practise the self inductance may actually decrease. The fact that in practise when two such material rings coalesce (the single ring having double the original current per ring) the flux will be somewhat less than double that of a single ring, (because both the cross section and the current have been doubled) shows that the self-inductance may be even still less than a half.

In the case of the attraction of two permanent magnets, it seems self-evident that not only the total flux energy but the total flux itself, of the combination, is *less* after the motion than before, thus disproving the older law that it always increases. At the neutral part of such a magnet, if it is a good one, it is presumably saturated, hence after they are in contact the flux in that part of each one cannot be assumed to have practically doubled, which would have to be the case if the total flux did not change, or more than double if it increased with the motion.

Prof. Brown's tests confirmed this in the following way though he says the tests were somewhat crude. By the total flux in a U-shaped permanent magnet is here meant the flux in the magnet at its neutral point (at the curved part). This was measured approximately by means of a galvanometer and a coil around the keeper, while it was being attracted; call this F . The change of flux at the neutral point of one of the two like magnets was then measured while the other was moved into contact with the first; call this f . This quantity f was found to be less than F , showing that the total flux of the combination was less after the motion than before, that is, less than double that of one magnet. Some flux as well as flux energy has therefore disappeared.

Bibliography

The following is a list of the writer's papers and articles bearing on parts of the subject matter of the present paper.

A Practical Limitation to Resistance Furnaces; The "Pinch Phenomenon." *Trans. Amer. Electrochem. Soc.*, Vol. 11, May 1907, p. 329.

An Imperfection in the Usual Statement of the Fundamental Law of Electromagnetic Induction. *TRANS. A. I. E. E.*, Feb. 1908, Vol. 27, Part 2, p. 1341.

A new Factor in Induction; the "Loop" vs. the "Cutting Lines of Force" Laws. *Elec. World*, Vol. 51, March 14, 1908, p. 559.

The Working Limit in Electrical Furnaces due to the "Pinch Phenomenon." *Trans. Amer. Electrochem. Soc.*, Vol. 15, May 1909, p. 255.

The Stretching of a Conductor by its Current. *Jr. Frank. Inst.* Jan. 1911, p. 73.

Formulas for Pinch Phenomenon. *Met. & Chem. Eng.*, Vol. 9, Feb. 1911, p. 86.

A New Type of Electric Furnace. *Trans. Amer. Electrochem. Soc.*, Vol. 19, April 1911, p. 255.

Electromagnetic Forces in Electric Furnaces. *Trans. Amer. Electrochem. Soc.*, Vol. 39, April 1921, p. 313.

Revision of some of the Electromagnetic Laws. *Jour. Franklin Inst.* Nov. 1921, p. 599.

Longitudinal Electromagnetic Forces. (Note). *Science*. Nov. 18, 1921, p. 492.

A Neglected Electromagnetic Force, *Chem. & Met. Eng.*, Mar. 15, 1922, p. 513.

A New System of Electromagnetic Forces Needed. *Jour. A. I. E. E.* April 1922, p. 305.

Electromagnetic Motions in Electric Furnaces. Paper read before the *Amer. Electrochem. Soc.* in April 1922; to be published in Vol. 41.

Discussion

ELECTROMAGNETIC THEORY AND ITS BEARING ON THE PINCH AND STRETCH PHENOMENA

C. O. Mailloux: The features of commanding interest in Dr. Hering's paper are the "pinch" and "stretch" phenomena, both discovered by him; and the difficulty of explaining these phenomena by the existing theories of electromagnetic fields is what has led Dr. Hering to urge the revision of these theories.

The discussion of the paper must, at the outset, recognize the polemic situation due to the very interesting and significant circumstance of the apparent antagonism to the paper, which has resulted from the necessity of questioning the completeness and adequacy of certain theories, notably those of Maxwell, in regard to electromagnetic fields, because, as will be seen, the limitations of Maxwell's theories are of the greatest importance in this case. It is as if it was not known that flaws have been found, even in great numbers, in Maxwell, years and years ago, and by men who were Maxwell's peers,—Hertz, Henri Poincaré, Helmholtz, Heaviside, Bjerkness, etc. When facts and theories fail to agree, the theories usually have to yield ground in the end. It is the speaker's opinion that the facts have the best of it in this case.

It seems hard to believe that any teacher could expect unquestioning faith in Maxwell today, in the light of the commentaries and revisions made by the men just named, to mention no others. For over twenty-five years Maxwell's treatise, though a great classic, and a valuable work of reference, has been obsolete as a text book, and as a means of presentation of Maxwell's own theories. The reasons for this were made very clear by the very man—Hertz—whose research work on electric waves supplied experimental evidence of the accuracy of Maxwell's electromagnetic theory of light, and helped to prove that

theory.² Hertz's two papers on the "Fundamental Equations of Electromagnetics," published in *Wiedemann's Annalen*, in 1890, (and which constitute Chapters XIII and XIV of the English translation published in 1893), were an attempt to simplify and clarify Maxwell's equations and to make them more consistent with Faraday's fundamental idea that the "field of action" of energy was an intervening medium known as the ether. As Hertz put it, Maxwell frequently wavered between the conceptions that he found in existence and those at which he arrived himself. Hertz points out that between the concept of direct action at a distance, springing across space, and the concept of an action which is propagated from point to point in a hypothetical medium, four distinct methods of reasoning and mathematical treatment can be distinguished, and that Maxwell, in different parts of his treatise, leans towards two of these modes of thought, each involving a different conception of "electricity." He says: "And so, unfortunately, the word 'electricity,' in Maxwell's work, obviously has a double meaning." After giving the two meanings, he adds: "If we read Maxwell's explanations and always interpret the meaning of the word 'electricity' in a suitable manner, nearly all the contradictions which at first are so surprising can be made to disappear. Nevertheless, I must admit that I have not succeeded in doing this completely or to my entire satisfaction."

Poincaré expressed a similar opinion in his discussion of Maxwell's theories in Vol. I of his "Electricité et Optique." Also see on this point Poincaré's "La Science et l'Hypothèse," page 250 and page 259.

While Maxwell is always given the highest credit by all authorities for the marvelous gigantic work done by him as a pioneer in the development, formulation, and demonstration of new theories and principles, it is admitted generally that his work was not so complete and perfect as to require no ulterior revision or modification.

The work of revision of Maxwell's equations was begun as early as 1885 by Heaviside, and the importance and value of Heaviside's contributions are admitted by all those who have participated in the work since then. For twenty years or more it has been considered necessary, in order to obtain a complete understanding and a satisfactory interpretation of Maxwell's theories, to discard Maxwell's own methods, and to resort to more modern methods of presentation which include the ideas of Heaviside, of Hertz, Poincaré and the other eminent authorities who have gone into the subject exhaustively. The study of Maxwell without the guidance of these authorities is apt to be misleading and harmful. Admiration of the magnificent structures erected by the genius of Maxwell does not make it a duty for his admirers to close their eyes to certain defects in these structures, or to insist upon their being also acknowledged as perfect anyhow. We would not proceed far before realizing the absurdity of such a policy.

Thus, Hertz has called attention to rudimentary ideas of a physical and of a mathematical nature ("vector-potential," being cited as an example of the latter), used by Maxwell, which are now regarded as being superfluous and really encumbering scaffolding. He says, significantly, that there is no object in replacing the *forces* themselves by *potentials* unless a mathematical advantage is gained thereby. He sees no such advantage in the introduction of the vector-potential in the fundamental equations; and he adds:

"Furthermore, one would expect to find, in these equations,

2. Although Hertz was one of the first workers in this field, his first experimental determinations of the velocity of propagation of electromagnetic waves gave erroneous results—only about 200,000 km. per second (instead of 300,000)—which threw serious doubt upon the correctness of Maxwell's equations. Blondlot, in France, was the first physicist to obtain experimental results by two independent methods that were in complete accordance with Maxwell's theory. Hertz' experiments confirmed these results subsequently.

relations between the physical magnitudes which are actually observed, and not between magnitudes which serve for calculation only."

It is for such reasons that vector-potential has been eliminated altogether, and that other concepts have been modified in the modernized form of Maxwell's equations.

Having thus brought out the now recognized fact that Maxwell's work was *not* invulnerable, but that it *was* weak in spots, and has had to be retouched, we may next consider the fundamental limitations of the Maxwellian theory, to see if perhaps too much has not been expected of it.

Poincaré, the peer of all his contemporaries in pure and applied mathematics, and the greatest genius of all time in mathematical philosophy and logic, said:

("La Science et l'Hypothèse," page 240):

"Maxwell does not give a mechanical explanation of electricity, and of magnetism.

He merely shows that such an explanation is possible."

The notes obtained from some courses of lectures on Maxwell's theories presented in the revised form above mentioned, which the speaker attended many years ago, as a graduate student, contain the following interesting commentary:

"It should be stated and understood at the outset that the Maxwellian theory does not tell us anything of the true ultimate nature of electricity and magnetism, or of electromagnetic processes. What it tells us is how certain vectors, namely, vectors of electric and of magnetic force and flux, vary in space and in time. It furnishes a fairly complete *geometrical* theory of the space and time relations of these vectors and of the forces or fluxes which they represent. While it tells us of these things to a satisfactory degree of completeness, it gives us only limited information—satisfactory as far as it goes, but not going far enough—regarding the *dynamic* theory of these forces and of the phenomena in which they are involved."

These views were confirmed and corroborated in convincing manner by Prof. V. F. K. Bjerknes, in his lectures on "Fields of Force" delivered at Columbia University in 1905, which the speaker attended. In his introductory remarks (See the printed account of these lectures, Publication One of the E. K. Adams Fund for Physical Research, *Columbia University Press*, 1906), Prof. Bjerknes said:

"The idea of electric and magnetic fields of force was introduced by Faraday to avoid the mysterious idea of an action at a distance. After the victory which Maxwell's theory gained through the experiments of Hertz, the idea of these fields took its place among the most fruitful of theoretical physics. And yet if we ask, what is an electric or a magnetic field of force? No one will be able to give a satisfactory answer. We have theories relating to these fields, but we have no idea whatever of what they *are* intrinsically, nor even the slightest idea of the path to follow in order to discover their true nature. Above all other problems which are related to fields of force, and which occupy investigators daily, we have, therefore, the problem of fields of force, namely, the problem of their true nature."

The method of research followed by Prof. Bjerknes consisted in generating what he termed "*hydrodynamic*" fields of force in masses of water by means of motion of vibratory nature, produced by pulsating and oscillating bodies, and then tracing analogies between the phenomena of attraction and repulsion produced in these "hydrodynamic" fields and those produced in electric and magnetic fields. By means of beautiful experiments he showed that the lines of magnetic force in a magnetic field can be represented in perfectly analogous manner by lines of oscillation in a hydrodynamic field. The hydrodynamic field experiments produced phenomena resembling magnetic attraction and repulsion so closely as to suggest a very close analogy, if not an identity, between the physical principles involved in both cases; and explanations of electric and magnetic phenomena were sought by the aid of these analogies. It was found, how-

ever, that the analysis and interpretation of the phenomena was much less difficult in the case of the hydrodynamic field than in the case of the electric and magnetic fields. Prof. Bjerknes says:

"The extent of our knowledge of the different kinds of fields differs greatly. All the properties of the hydrodynamic fields follow directly from the most trustworthy laws of nature, that is from the principle of the conservation of the mass, and from the principles of dynamics. With reference to electric or magnetic fields, on the contrary, we have only formal theories. First we have an extensively developed *geometric theory of the distribution in space of the vectors*, which describe the field. And then, in a more or less superficial connection to this geometric theory, we have a very much less developed theory of the dynamic properties of the fields.

Taking the facts as they lie before us, we shall be obliged, therefore, to give to our theory a dualistic form, comparing separately the geometric and the dynamic properties of the two kinds of field. It may be reserved for the future to penetrate to the central point, where the geometry and the dynamics of the question are perfectly united, and thus make the comparison of the two kinds of field perfectly easy."

In reference to the dynamics of the electric or the magnetic field he says:

"Our knowledge of the dynamics of the electric or magnetic field is very incomplete, and will presumably remain so as long as the true nature of the fields is unknown to us.

"What we know empirically of the dynamics of the electric or magnetic field is this:—bodies in the fields are acted upon by forces which may be calculated when we know the geometry of the field. Under the influence of these forces the bodies may take visible motions. But we have not the slightest idea of the hidden dynamics upon which these visible dynamic phenomena depend."

Faraday's idea, for instance, of a tension parallel to, and a pressure perpendicular to the lines of force, as well as Maxwell's mathematical translation of this idea, is merely hypothetical. And even though this idea may contain more or less of the truth, investigators have at all events not yet succeeded in making this dynamical theory a central one, from which all the properties of the fields, the geometric, as well as the dynamic, naturally develop, just as, for example, all properties of hydrodynamic fields, the geometric as well as the dynamic, develop from the hydrodynamic equations. Maxwell himself was very well aware of this incompleteness of his theory, and he stated it in the following words:

"It must be carefully borne in mind that we have only made one step in the theory of the action of the medium. We have supposed it to be in a state of stress but have not in any way accounted for this stress, or explained how it is maintained. I have not been able to make the next step, namely, to account by mechanical considerations for these stresses in the dielectric."

In spite of all formal progress in the domain of Maxwell's theory, these words are as true today (1905) as they were when Maxwell wrote them.

In reference to the geometric properties of electromagnetic fields according to Maxwell's theory, Prof. Bjerknes says:

"Our knowledge of electromagnetic fields is contained in what is generally called Maxwell's theory. This theory does not tell us what electromagnetic fields are in their true nature. It is a formal theory, bearing upon two aspects of the properties of the fields. What are called Maxwell's equations give a very full description of the variation from time to time of the geometric configuration of electromagnetic fields. To this geometric theory is only feebly linked the much less developed theory of the dynamical properties of these fields."

In reference to the geometric description of electromagnetic fields, Prof. Bjerknes says:

"To give this description, a series of special electric and special magnetic vectors has been introduced.

"We believe that these vectors represent real physical states existing in, or real physical processes going on in the medium which is the seat of the field. But the nature of these states or processes is perfectly unknown to us. What still gives them, relatively speaking, a distinct physical meaning is, as we shall show more completely in the next lecture, that certain expressions formed by the use of these vectors represent quantities, such as energy, force, activity, etc. in the common dynamical sense of these words. These quantities can be measured in absolute measure. But their expressions as functions of the electric or magnetic vectors contain always two quantities of unknown physical nature. When once the discovery of a new law of nature allows us to write another independent equation containing the same unknown quantities, we shall be able to define perfectly the nature of the electric and magnetic vectors, and submit them to absolute measurement in the real sense of this expression. Provisionally, we can only do exactly the same as does the mathematician in problems where he has more unknowns than equations; viz. content ourselves with relative determinations, considering provisionally one or other of the unknown quantities as if it were known. But we retain the symbols for the unknown quantities in all formulas bearing upon the pure theory of electromagnetic phenomena, for this will be the best preparation for the final solution of the problem."

"This imperfect knowledge is, of course, also the reason why our theory of electromagnetic fields is split into two different, loosely connected, parts; first the geometric theory of the fields, where the relation of the vectors to time and space is considered independently of every question of the physical sense of the vectors; and, second, the dynamical theory of the fields, where the question of the nature of the vectors is taken up, but only imperfectly solved."

If we bear in mind the obviously electrodynamic nature of the new phenomena mentioned in Dr. Hering's paper, and for which the classic laws of electromagnetism fail to give an adequate explanation even when they are strained by more or less sophistic expedients (sliding contacts), we can appreciate the force of the preceding comments of Prof. Bjerknes upon the limitations of Maxwell's theories from the electrodynamic point of view. Indeed, in the opinion of the speaker, the burden of proof may be considered as having been thrown back upon the Maxwellites, meaning those of the orthodox school, because the Maxwellites of the reformed school would have been less militant, precisely because they are informed in regard to the flaws, the gaps, and the weak joints in electromagnetic theory as it stands today. It is dangerous in physics, as in other things, to claim more than the physical facts will warrant. The true office of physical laws is to explain physical facts and not to contradict them or deny their possibility.

The reference made by Bjerknes to Faraday's idea of a tension parallel to, and a pressure perpendicular to, the lines of force in a magnetic field, indicates that he attached much importance to further development of a dynamic theory based upon that idea, in a manner that would make it possible, as he says, for all the properties of magnetic fields, both *geometric* and *dynamic*, to be developed *naturally*. Dr. Hering comes very close to Bjerknes when he expresses the belief that a satisfactory theory could be based on the assumption of only a single magnetic force, the tension along a line of force, the other property, the repulsion of like lines, being then deduced from the first.

Unfortunately, this is easier said than done. We may see the goal that it is desired to reach, but as Bjerknes well said: "We have not even the slightest idea of the path to be followed in order to attain it."

The trouble appears to be that the specification of the physical characteristics and properties of magnetic fields is not yet complete. That is why, as Bjerknes says, we have more unknown

quantities than equations. Nevertheless, Dr. Hering's paper contains many suggestions and cautions that will prove of great value, as a means of keeping on the right track whenever we do succeed in finding an entrance to the right path. The paper is filled with ideas, the complete discussion of which, in some cases, would lead us far into physical and philosophical problems of more or less abstruse character.

With regard to the stretch phenomenon, which seems to be the principal cause of objection to Dr. Hering's views, it may surprise those who dispute its existence and even its possibility on Maxwellian or other theoretical grounds, to learn that two very distinguished disciples of Maxwell, Mascart and Joubert, disagree with it very seriously. This may be due to the fact that the treatment of electromagnetism in their own celebrated classical treatise on "Electricity and Magnetism" does not follow Maxwell very closely, but follows more the French School of Physics. In Volume I, Part IV, Chapter I, Paragraph 455, after the statement that "the action of a current upon itself, can also produce deformations or continuous motions," some experiments with a movable portion of circuit are described; and the discussion ends with the following significant remark: "If the wire is elastic it will *stretch* until its elasticity balances the electromagnetic forces."

This may be considered expert opinion of highly qualified and competent character in defense of Dr. Hering's views.

Dr. Hering's suggestion that the mathematical theory should avoid integrations around complete circuits and should, instead, be based upon limited portions or elements of circuits, is of great importance. He sees the same dangers in going too far, or beyond proper limits, that occurs in the case of the mathematics of the soap bubble film, mentioned in the paper, in which a formula that is quite rational for finite values of the radius of the bubble, becomes "insane" when the radius is increased to infinity. This is a matter of such importance, and similar cases of mathematical insanity are so frequent, that it is worth while to call attention to the simple means of preventing it, namely: "*Beware of absolute infinity*," "*No thoroughfare here*." That is perhaps the first thing that every student of mathematical physics should learn by heart. It is the one and only unfailing preventive of that form of insanity. It may be consoling to learn that many of the greatest mathematicians that the world has known were not free from attacks of that form of insanity; but that is no excuse for not taking measures to stamp out the disease.

Ask any student to draw two right lines, one perpendicular to the other, at or near its middle, and then to imagine both lines to be prolonged indefinitely; and ask him if he can possibly conceive that as the two lines were increased in length, there is at any stage even a faint resemblance of the T to a sector of circle. He will say "no." Let him, now, start with a small sector of circle, and let him imagine the radius of the circle to be increased indefinitely; and then ask him if, ultimately, the arc of the circle will become a right line. The chances are that he will answer "yes;" although the correct answer should be: "There can be no circle whose periphery is a perfectly right line." What is the reason for this error? In the first example, the mind was left free to see and to reason; in the second example, the mind was hypnotised by a question which assumed the possibility of doing something that is impossible physically, metaphysically, and mathematically, for human beings, namely, the crossing of the abyss that extends from the limits of the finite to the infinite. That impossible kind of circle is the hypothetical "circle of Pascal" whose center is everywhere and whose circumference is nowhere. The limit of the finite is only a *relative* infinity. The other is an *absolute* infinity. The relation between these two kinds of infinities has been treated exhaustively in the work of Henry Fleury ("Théorie rationnelle de l'Infini mathématique et du Calcul Infinitesimal," Paris 1899, pp. 324). Under the heading of "Properties of Infinity"

lecture, and I still adhere to it as being, in my opinion, somewhat more appropriate, and I have believed, for a long time, that when the mathematical theory of elasticity shall have been developed to a sufficient point, we shall have all of the data necessary for working out a perfect theory of magnetism. In other words, I believe that magnetism is nothing more than a manifestation due to the elasticity of the surrounding medium, that it is an elastic disturbance, and I may state, in passing, that it is here that I differ with the conception advanced by Faraday and Prof. Thomson as to the shortening of the lines of force. I think that the idea of shortening is rather vague. I hardly think that we can say that lines of force shorten as such. It would probably be more appropriate to express it in some other way. What seems to us to be shortening is probably merely the manifestation of some other phenomenon. Another point is the snapping of the lines of force. I shall endeavor to present some experiments which illustrate the fact that lines of force do snap and break, as I did in the lecture of 1883, and that the snapping is not simultaneous."

These remarks would need very little modification today, so far as their *substance* is concerned. They might be amplified somewhat so as to make clear what were (and are still) the speaker's views in regard to the so-called "shortening" of lines of magnetic force. There was also a slight error in saying that lines of magnetic force "break" without explaining more fully what was meant. The fact is that lines of magnetic force do not "break" in the sense of being severed or parted like a string or a wire that is broken into two pieces; but they may *break away* and be parted from an "anchorage" such as from an iron armature which is moved in front of the poles of a magnet or in any magnetic field. That "break away" movement is sudden or "snappy," but it does not occur simultaneously for all the lines of force in a given portion of magnetic field; it occurs for each "vortex" by itself when the conditions are right for that vortex or line of force.

The additional details promised were not sent in, partly from lack of time, but mainly from a realization of the importance of reviewing the whole subject fully before adding to the extempore discussion referred to.

The earliest conjectures of the speaker, as outlined in 1879 (in the unpublished paper mentioned in the previous A. I. E. E. discussion) are not without interest on this occasion, when it is desirable to gather together all ideas that may prove helpful. These conjectures were:

That lines of magnetic force were elastic like steel rings or hoops; that they tended, normally, in a homogeneous diamagnetic medium, to take the form (figure) of perfect concentric circles; that any departure from the circular concentric form was, in a sense, abnormal, being due to disturbing conditions and forces, and that it was always attended by reactions which tend to restore the circular form; that there was a limit to the extent to which they could be swerved or distorted from the circular form; and that, at the limit of distortion, they would "break away" and assume a more circular ("normal") form, and would do so in a sudden, snappy manner as if they were *resilient*, and recoiled like an elastic ring that has been distorted and is suddenly released or else suddenly breaks loose from the distorting force that was acting upon it.

The process of reasoning followed was as follows:

If a hoop made of tempered steel wire forming a perfect circle is distorted in any way and then released suddenly, it will instantly recover the form of a perfect circle. A perfectly elastic steel hoop would be a good physical model of a line of magnetic force or of a bundle or coil of such lines, in regard to the manner in which it is influenced by, and reacts upon, outside forces; but such a model is incomplete and inadequate for the representation of the reactions which the magnetic field itself exerts upon the forces producing it. According to Newton's principle, dynamic action and reaction are always equal and

opposed to each other. On the theory that, in this case, an elastic disturbance is produced in the ether surrounding an electric conductor, a line of magnetic force may be regarded as being a dynamic *reaction* against some dynamic *action* which is exerted by the electric current passing through the conductor. If we picture the action at each line of force as comparable to that of a conical wedge which is forced into a rubber ring, then the *reaction* is made intelligible to us as a state of tension which causes the ring to be stretched into a larger, thinner ring; and the tension thus produced is the complete measure of both the reaction and the action. If the action is increased, the reaction will increase enough to balance the action and the rubber ring will be expanded into a still larger circle. If the action decreases, the ring will shrink in size until the decreased reaction in the new state of stretch balances the reduced action. This is what the speaker had in mind when he said (in the A. I. E. E. discussion in 1890) that we can hardly say that lines of force shorten as such, and that the shortening is probably the manifestation of some other phenomenon. The phenomenon which he had in mind was the *elastic reaction of the medium* against the action of the current producing the lines of force. In this case, the "action" is, in all probability, different from that represented by a mechanical pressure exerted radially like the pressure exerted by the conical wedge above mentioned; and, consequently, the reaction is entirely different from that represented by the tension of a stretched rubber ring. The speaker early acquired the habit, which he has never lost, of using elastic steel rings as a mechanical model or analogy in explaining magnetic action. Thus in a note-book under date of August 11, 1889, we have:

Theory of Magnetic Attraction and Repulsion (based on experiments of 1879), (with two diagrams):

"Taking two conductors parallel to each other and carrying currents, as the simplest illustration, we have:

- 1st, attraction when the currents are in the same direction;
- 2nd, repulsion when the currents are in contrary directions.

(1) In the first case, I regarded the attraction as due to the blending of the magnetic circuits into one circuit, as shown in the sketch, and the effort made by the resultant circuit to assume the concentric circular form. In other words, when there is only one conductor it tends to maintain itself in the center of the vortex; when there are two or more they tend to go to the center of a combined or resultant vortex, and consequently to come together.

In such a case I can conceive that, instead of being shortened, some of the lines immediately surrounding the conductors, might be on the contrary actually stretched or distended. In fact, they would all be in a sense stretched as long as the vortex did not resume the perfect circular form.

(2) The second case (of repulsion), I regarded as that of the compression of a steel hoop or ring, by contact with another steel hoop or ring, with the conductor impelled as before to maintain itself central with respect to the rings, and being consequently, urged in a direction opposite from attraction. In this case, we might consider that the lines of force act rather by expanding than by contracting or shortening."

In a note made the next day, the concept of a vortex-like disturbance of the ether is introduced.

The vortex-motion theory always was interesting to the speaker largely because it is a *kinetic* theory. He believes, with Maxwell, Shelford-Bidwell, and others, that kinetic theories of magnetism are the only ones that will stand serious scrutiny. Even in a medium which is infinitely tenuous like the ether, kinetic energy can still be developed in measurable quantities, since the decrease in mass can be made up by an increase in velocity. In the formula $E = mv^2/2$, the value of E will remain constant as long as the product mv^2 remains constant, and when the mass (m) is reduced to $1/n$ of its value, the velocity (v) does not have to be increased n times but only the *square root* of n times. Now the elastic properties that make lines of

John H. Morecroft: Dr. Hering's paper is rather difficult to discuss, as he makes so many ambiguous and general criticisms of our present laws, trying to show their inadequacy, but never apparently doing so, when one analyzes his methods. Such ideas as conveyed by the expressions "reactions of these forces on each other, or on a foreign force" and "abutments or anchorage of the forces in a field" certainly do not tend to clarify his arguments.

When one conceives of the electric current as moving electrons, as he is evidently beginning to do, it seems rather inappropriate to speak of the energy of the magnetic field as potential energy, as he does; this energy is due entirely to the motion of the electrons and so would naturally be classified as kinetic energy, while the energy of the electric fields of the electrons, present when the electrons are stationary, is better called potential energy.

The whole paper is so full of ambiguities and misleading statements that a complete discussion is out of the question, but an analysis of a few points Dr. Hering brings up is attempted in the following notes.

In discussing Fig. 1, in his paper he apparently thinks that the idea of current flowing in such a circuit is a new one; it seems well to point out therefore, that every time he telephones he is probably sending his voice current through just such a circuit, and that the telephone engineers use circuits of this make-up probably more than any other kind. The circuit of his Fig. 1 is closed through a condenser, the two plates of which consist principally of the two spheres *A* and *B*; the ordinary telephone

FIG. 1

circuit is closed in just the same manner, but there the condensers have a somewhat larger capacity than is the case in Fig. 1. In spite of this statement to the contrary, it is necessary to consider every circuit closed, if we wish to calculate how much current will flow in it; what seems to constitute an "open circuit" in his Fig. 1 is rather a capacitive reactance between plates *A* and *B*, a reactance so high for ordinary frequencies that negligible current can flow and so it is classed by engineers dealing with ordinary power circuits, an open circuit. But there is no real distinction between an open circuit and a closed circuit, from the theoretical viewpoint; current will flow in any circuit in which there is electromotive force acting, especially if this is an alternating e. m. f.; the amount of current may be so small that its effects are negligible and the circuit is therefore called open. Actually the same law of current flow holds good for all circuits.

In such a circuit as that of his Fig. 1, this current would be so small in the ordinary test as not to be measureable and so the circuit is said to be open; if however a frequency of one hundred million cycles is used the capacity reactance of the condenser *A-B* is sufficiently low to permit the passage of measurable current and so the circuit would not be called open; the writer sees no reason at all therefore for any argument about this circuit; it follows the ordinary laws of circuits, as do all the rest of his circuits, one or two of which will now be discussed.

To clarify somewhat (even though only a little) some of the material presented in the paper, and to show how the author of the paper thinks and reasons, I will recall an argument he presented about fifteen years ago; I hope he will bear with me for so as the experiment he then described contains what

seems to the writer a fallacy, which fallacy is present in some of the experiments contained in the present paper.

Can a circuit, being linked with some magnetic flux, be unlinked from this flux without having a voltage induced in it? That was the question Dr. Hering put to himself, and his answer was—Yes, arrived at as a result of the experiment now to be described.

His experiment was arranged about as shown in Fig. 1. An electric circuit consisting of the galvanometer *G*, two flat brass springs *D, D*, fastened to a wooden block *C*, and in contact at *E*, is linked with all of the flux through a bar magnet, shown in section at *A*. Around the bar magnet is fitted a smooth brass ring *B*.

By pulling block *C* (towards the right in Fig. 1) the springs

FIG. 2

D-D come in contact with ring *B*, further motion in the same direction opens the contact at *E*, and still further motion carries them around the ring, until they finally slide over the ring and again come in contact on the right side of the ring. This sequence of events is suggested in Fig. 2. In Fig. 1 the circuit evidently is linked with the magnet's flux, and in condition *c* of Fig. 2 it evidently does not, and hence, as the galvanometer has shown no deflection during the progress of this ingenious experiment, the author would have us conclude that a circuit can be unlinked from magnetic flux without having an e. m. f. induced in it. The results of this experiment, however, constitute no reason at all for the conclusion; our old ideas about changing interlinkages generating e. m. f.'s. are just as trustworthy after the experiment as before.

FIG. 3

It will be seen that in position *a* Fig. 2 there is no longer a circuit involved in the argument, but there are *two* circuits, one of which (springs and left hand side of ring) still links with the flux and another (springs and right side of ring) which does not link with the flux. So, the experimenter has replaced a circuit by *two* circuits, *one of which does not link with the flux at all*.

I suggested at the time that the audience would understand the experiment better if it were performed as suggested in Fig. 3, the sequence of events being exactly the same as it was before, but the various steps being somewhat more evident. A circuit shown by the full lines of Fig. 3 links with the flux of magnet *A*; the wire of which the circuit is comprised being

must think accurately, not confusing one circuit with another—he must not be willing to apply a law to a case which involves premises which the law does not. It seems to the writer that the older laws, about which doubt was supposed to be cast by these experiments, are rather substantiated by them.

John Mills: I have had no opportunity unfortunately to try out any of these experiments. I approach the problem very much from the standpoint of the remarks of past President Mailloux and I wish to use the occasion to arouse a further interest in the mechanisms which underlie the phenomena Mr. Hering describes.

I think Mr. Hering's interesting paper should be approached in the spirit of one who recognizes that the past twenty-six years, since J. J. Thompson identified the electron, have been revolutionary and scientific concerts. He calls attention to a much needed reconsideration of our formal expression and exposition of electro-magnetic phenomena. Today, we have electronic mechanisms which Maxwell and his immediate successors did not have. Today the ether is the most debatable assumption and energy and an electrical matter are the two entities with which the electronic physicist deals most consciously. With Mr. Hering's fundamental appeal for recognition in our expositions of underlying mechanisms I am most heartily in accord. I have tried some missionary work along that line myself but with relatively small success.

Without any regard to the criticism which can be directed towards the experiments which Mr. Hering has presented let us consider his Fig. 4, and look at it without reference to the inductance. Imagine billions of electrons rushing along from the negative terminal of the battery, along the connecting wire and plunging into the liquid of the trough. Then remember that each of these electrons is about $1/1845$ of the mass of a hydrogen atom. Remember that for the currents used there would be about a thousand billion billion of these electrons taking that plunge each second. Now I simply raise the question: Is it inconceivable that, as they do plunge, they should kick back on the slider? I do not believe it is inconceivable,—and I cannot see—and here is where I differ and am unpopular—I cannot see that flux and other Maxwellian concepts enter into the problem at all.

Whether or not, however, these electrons, in their obedience to Newton's third law of equal action and reaction will result in a perceptible motion of any given slider is a question that the electronic physicists can answer for us, either from data at hand or by simple but refined researches.

I admit our knowledge is incomplete, but it seems to me our knowledge has to be expressed in terms of the electron of which we have heard for twenty-six years. We may apply the same ideas to other figures of the paper by Mr. Hering and reach similar conclusions. In each case, however, the problem is one of electrons and is not a problem of flux nor a problem of "stretch effect." If there is a stretch effect it must be explainable on an electronic basis.

Two of the experiments, namely those of Figs. 3 and 6 are conceivable upon the electronic basis mentioned above but require a recognition of the fact that because the shape and sizes of the vessels, into which the moving wire dips, are dissimilar there will be possible dissimilar conditions of turbulence due to thermal effects. One could have wished that Mr. Hering had approached this investigation more directly from the view point of electronics and obtained quantitative results.

H. G. Brinton: In connection with the subject of fundamentals, I would like to say a few words about fundamental electric fields and the electron theory.

The electron theory is not completely perfected. There are some phenomena which it has not yet explained, although it is accepted as our most fundamental theory and deals with the constitution of matter as well as electric and magnetic phenomena. The phenomena of gravitation and of the propo-

gation of electromagnetic waves through space are two of the most interesting cases of unexplained phenomena. There is also need for more clear and fundamental explanations of other phenomena, as pointed out by Dr. Hering. These unsolved problems make a consideration of the fundamental theory still more fascinating. I have made a study of this subject as a matter of personal interest and have worked out a development of the electron theory which affords a basis for the explanation of gravitational as well as electromagnetic phenomena.

The point of view of this discussion is based on the idea or fact that we have no conception of the ultimate essence of electrons, protons, and fields of force. We only know how they act. The human mind has not been capable of going further than that. What is spoken of as "knowing the ultimate nature of matter" can only consist, under present conditions at least, of a detailed knowledge of the nature of the behavior of the smallest units. We consider matter as made up of a large number of fundamental units. From this point of view, an explanation of complex phenomena involving fundamental units, will be a statement of the actions taking place, in terms of the actions of fundamental units and in accordance with fundamental laws. The things we now consider most fundamental cannot now be explained in terms of anything more fundamental, but our ideas in regard to what is most fundamental are subject to change. Our fundamental ideas must be judged by their consistency with each other and by their utility as a basis for explanation.

The fundamental units of matter should involve electrons and protons in some way. Since we regard electrons and protons as primarily centers or terminals of fields of force, it seems logical that the fundamental units should involve electric fields of force. Let us therefore take, for a fundamental unit, the field of force extending from a single proton to a single electron. We will retain the idea that electrons and protons maintain their identity and assume that the fundamental unit fields of force maintain their identity under all conditions. There is such a field of force extending from each proton to every electron. What we usually have called an "electric field" must now be called a "resultant electric field" to distinguish it from the fundamental unit electric fields.

We have to consider next the inter-action of these fundamental fields. The action of a single field needs no description here. Let us consider the case of two positive particles with fields directed outward from each particle, or the case of two negative particles with fields directed inward to each particle. In these cases the adjacent fields are in the same direction or have components in the same directions, and we know that there is a resultant force tending to move the two particles apart. We may, therefore, say that two adjacent fundamental fields in the same direction tend to move apart. This is the same action that takes place within a single field. If one field is superimposed on another field having components in the same direction, but of varying intensity, the first field tends to move away from the stronger part of the second field as a result of the combined actions of adjacent parts of the fields. This resultant action is what determines the direction of the resultant force tending to move two positive particles or two negative particles away from each other.

In the case of two particles, one of which is positive and one negative, we have fields directed outward from the positive particle and fields directed inward to the negative particle. In this case the two adjacent fields have components in opposite directions and we know that the two particles tend to move together. To be consistent, we must say that two fields having components in opposite directions tend to move together. This is the direct opposite of the action between two adjacent fields in the same direction. There is, however, another action to consider in the case of a positive and a negative particle. In addition to the fields referred to above extending to and from the

zero initially then they must remain zero, whatever else happens, so long as the rings are closed and have zero resistance.

Therefore, the deductions in the appendix are wrong. The magnetic linkages cannot decrease or increase in a closed ring without resistance.

Inasmuch as the equations used by the author assume the validity of the above equations, the conclusion would seem to be clean cut.

It may be of interest to further point out that the author's proposed law is merely a specialized re-statement of the commonly applied principle that the electromagnetic force *acting on* any part of a circuit is

$$f = 1/2 i^2 \frac{dL}{dx}$$

where, $\frac{dL}{dx}$ = the rate against distance, not time, at which

the total inductance of the circuit would change if motion of that part of the circuit occurred in the direction of the force.

i = instantaneous value of current.

The author's proposed law is: "in an electromagnetic system in which the current is being maintained by a source, any and only such mechanical motions of the conductor will tend to take place as will generate a counter e. m. f. somewhere in the circuit."

The counter e. m. f. which the author defines here is,

$$e = i \frac{dL}{dt}$$

Of course if there are circuits in inductive relation to the one in question, the force is given by

$$f = 1/2 i_1^2 \frac{dL_1}{dx} + \sum i_1 i_2 \frac{dM_{12}}{dx}$$

and the counter e. m. f. referred to, is given by

$$e = i_1 \frac{dL_1}{dt} + \sum i_2 \frac{dM_{12}}{dt}$$

Furthermore, using the above familiar expression for force, it is easily demonstrated that it is not necessary to assume, as the author does, the special case of constant current. The expression gives the force existing for the particular current, whether the latter is rapidly varying or constant.

In other words, the proposed law is not new, and hardly merits the name of a *law*, for it is merely a re-statement, with an unnecessary limiting condition, of a long established corollary of the Law of Conservation of Energy, from which the above mathematical expression at once follows.

Thus to summarize, all of us will probably agree that, for the profession, it is a wholesome and commendable thing to review and question, as the author has done, the validity of our fundamentals, and to demand an explanation of certain observations which appear to him to be in contradiction to the so-called *laws*. However, I do not agree that he has demonstrated the invalidity of the law of electromagnetic induction in the particular application of determining forces. On the other hand, the fundamental assumptions involved in the equations given in the Appendix, contradict the conclusion there arrived at. Also, the proposed new law is merely an incomplete re-statement of a well-known corollary of the Law of Conservation of Energy.

E. H. Kennard: Dr. Hering's paper arouses in me very mingled feelings. With his criticisms of the textbooks I feel compelled to sympathize to a considerable degree. The writers of textbooks ought, I think, to remember that their books are to be employed more or less as reference books and the text to be so written that it cannot be misunderstood by any

attentive and thoughtful reader. Every exception or restriction upon the scope of a law ought to be mentioned, at least in a footnote. And then, besides imperfections of statement, many books contain a distressing number of genuine errors. But to err is human and we shall never see perfect books.

Let us take up Dr. Hering's chief points in order.

1. *Do circuits tend always to increase their flux?* I think that they do; Dr. Hering's own experiments confirm this law. Of course, in calculating the change in flux one must imagine the current to be kept constant. This assumption will be found to underlie all deductions of the law, although I am afraid that textbook writers do not sufficiently emphasize the point.

In Dr. Hering's Fig. 5, a careful study of the flux shows that the motion increases the flux no matter on which side the battery is placed, for when we flop the circuit over to the other side of the mercury troughs we reverse the direction in which a line of flux must be called positive as it passes through the plane of the paper, and this reversal compensates for the change in the location of the area enclosed by the circuit.

What this experiment really shows is that a circuit does not always *enlarge* under the action of its own flux—and I must admit that some textbooks make wrong statements about this. I think that any plane circuit so shaped that it bends always toward the same side as we go round it, will always tend to enlarge under its own electromagnetic forces, whereas this may not hold if the circuit contains a part shaped like an S or a Z.

The law holds also for Dr. Hering's imaginary experiment in which two rings of no resistance have currents induced in them and are then brought toward each other; for the currents in the rings do not remain constant. We can write for each ring $L di/dt = -d\phi/dt$ where ϕ is the flux through the ring due to the current in the other one; this equation gives by integration $Li + \phi = \text{const.}$, which shows that the flux through each ring remains fixed forever. Hence as the rings approach and the mutual flux increases, the flux of self-induction, Li , must decrease, and so must the current, i . Thus the change in flux produced by the motion, which determines the mechanical force, is exactly compensated for by another change caused by the change in the current, and this is why the flux through each ring remains constant.

2. *A General Law of Motion.* Dr. Hering emphasizes two principles, (1) that potential energy tends to become kinetic, and (2) that no motion can be produced by electric currents, at least in the absence of iron, without the generation somewhere of an e. m. f. These two principles are, of course, well known both to physicists and to engineers, although the proposal to make them the foundation of the theory of electromagnetic forces is, perhaps, new. The merits of this proposal are a matter of opinion; for myself, I cannot feel that the proposal is a good one, but the subject is too large for discussion here.

3. *A longitudinal force* is not shown to exist by Dr. Hering's experiments, which are entirely explained by the accepted laws, as I shall show presently.

4. *Sliding Contacts are a Nuisance.* So they are. To the mathematical theorist every discontinuity or abrupt change in conditions is a nuisance and requires a special explanation. The usual practise among physicists (except, perhaps, among the French) seems to be to state the general laws of physics as if such discontinuities did not exist, and then to replace the discontinuous cases by an equivalent continuous one.

The law of induction I like to state in three steps as follows:

- (a) *Definition.* A circuit means a closed filament of matter.
- (b) The *E. M. F. induced* in any circuit (measured in electromagnetic units) equals the time rate of decrease of the flux that is linked with the circuit.
- (c) At a *sliding contact* one may imagine a thin layer of conducting liquid to be inserted between the sliding surfaces, so that there will be a continuous gradation of motion through this

who are not hidebound to traditions, and in the developments in new, formerly forbidden fields which now appear to be open to us.

Practically the only attack of importance by several discussers, concerns those old laws which are to the effect that there must always be an increase of flux and of self inductance when a system does mechanical work. These critics claim that I have denied the corrections of these laws. As there is no such denial in the paper, these critics in this case as also in several other cases in which I did not say what they are attacking, have merely set up a straw man in order to have something to knock down. Discussers ought to read a paper carefully before they attack it.

I had even admitted that in many cases these laws apply correctly, although in some a highly involved, very artificial, confusing definition of sliding contacts (like the very old one used in Prof. Morecroft's discussion), or other limitations, must be included to make them apply. Many misfits can be made to fit, and our ignorance be made to appear to be wisdom (at least to the unsuspecting student), by resorting to an involved definition of sliding contacts, especially when the student cannot understand the definition.

What I did claim, and do so still, now even stronger than before, as my opponents could not deny it, is that these laws are special case laws, and not the most fundamental or universal ones. A universal law is one which can have no exceptions, but these older laws have, as was clearly shown. To exclude these exceptions (and probably others also) it is absolutely necessary to read some limitations, restrictions or qualifications into the law, so that it will fit and not mislead; these, of course, make it a special case law, as it then admittedly does not apply outside of these limitations. This, of course, leaves us *without any law* for all cases outside of those limitations, which is the best proof that it is not a universal law. There may perhaps be very useful cases which are outside of these limitations. One of these proposed restrictions is "provided the m. m. f. does not change;" another is "provided there are no structural changes," yet in every motor there are continual structural changes of the circuit at the commutator. Moreover it is surely no crime to change the m. m. f. or make structural changes, if something useful may be gained thereby, and for these cases we had no laws. One of the chief purposes of this paper is to help those who desire to work in new and formerly forbidden fields.

In my opinion taking refuge behind a "sliding contact" to make misfits fit, is unscientific and a tacit admission that there is something wrong somewhere, either in the subject or in the teacher or book writer, when that old fashioned subterfuge becomes necessary. Sliding contacts used as a subterfuge in explanations can now be (as I have shown), and should now be, ruled out as obsolete, if they are not, the students have my sympathies. Moreover these laws seem to be taught so as to leave the impression in the mind of the student that such increase of flux and self induction were in some mysterious way the *cause* of the motion (which they are not, though in many cases they are incidental to it, due to the connected outside source of energy, as I showed), and that without such increase there could not possibly be any self produced motion; this is not true and ought not to be taught.

The self inductance (a purely geometric quantity) depends greatly on the number of turns, while the flux and flux energy (on which the forces depend) are quite independent of the number of turns being a function only of the ampere-turns; for the same ampere-turns and a given reluctance, hence for the same flux and flux energy, the self inductance may have very greatly different values when the number of turns is changed; to give the student the impression that the self inductance and the flux and flux energy always go hand in hand, is positively wrong. To define A in terms of B when B varies greatly with a factor that does not affect A , is *not* a proper definition. By combining the self inductance and the current as one quantity (representing

flux and flux energy) useful laws and undoubtedly correct calculations may be made, as admitted in the paper, but the student should by all means be told (though apparently he is not) that this is limited to special or restricted cases, and is not universally true; this was shown in the paper.

The presence of iron moreover increases the self inductance and the flux very greatly, yet the flux in the iron may not always be free to produce motions; an iron pipe around a centrally located conductor would presumably not increase either the pinching or the stretching forces, notwithstanding the greater flux and self inductance. Hence formulas based on self inductance may sometimes give wrong results.

The chief other point in the paper which the opponents attacked, though ineffectively, is the one concerning the two rings at nearly 0 deg. absolute, though no one has shown the statements made in the paper to be incorrect; this case shows clearly that the flux and flux energy *diminish* when there is self produced motion. In this case the two rings were, and must of course be, considered together as forming one system; to treat one ring and its linkages by itself, as some have done, leads to nothing new and useful, and is improper as one ring does not constitute the whole system.

The real purpose of this example was apparently lost sight of or was not grasped by the opponents, namely to completely separate an electromagnetic system, containing stored energy, from any outside source of new energy, in order to be able to study this stored energy alone and by itself without any interference by new energy. This can easily be done with electrostatic systems, but it is believed that this is the first time an experiment was devised in which this could be done with an electromagnetic system. Our old book laws (like the very old Kelvin law) were always based on the *united action* of two things, the stored energy and a source of new energy inseparably connected; never before (I believe) could the stored energy be experimentally studied separately, and this is very necessary in order to get at the real fundamentals. A single equation with two unknowns cannot give the values of each by itself, it is incomplete information; so is an experiment or law involving the inseparable joint action of two factors, as in the old Kelvin law.

The above answers the discussion in general. The constructive discussion of Dr. Mailloux is a contribution of value and importance. His remarks about infinity are especially important, as they explain the absurdities, inconsistencies and even serious fallacies arrived at by even able expert mathematical physicists when they have recklessly jumped into that dangerous abyss, infinity; and still worse, have then tried to force their unacceptable conclusions on to the more cautious thinker or on to the trusting, unsuspecting student, thereby tending to muddle his brain and to check progress. The bringing out of his discussion on infinity has been one of the useful fruits of the paper.

His references to the able work of some of the older French physicists who sometimes disagreed with Maxwell, will no doubt surprise the orthodox, hidebound, Maxwellians who seem to consider it a crime to even question anything which that admittedly brilliant mathematical physicist said 50 years ago, as though progress in science was not possible. The writer, who has discussed these subjects for years with many, has found that there are many progressive physicists who do not consider all the 50-year-old Maxwellian views to be incontestable today, and who admit that progress has since been made. Able physicists have admitted that the Maxwellian "complete circuit" restriction has long ago been abandoned as the most fundamental case and is now out of date and behind the times; it refers to a special case only (though the most usual one) and when so restricted is very useful. Today we must admit that an electron can start from rest at a point A , move to a point B and stop there, that is, it is no longer necessary to involve all the other electrons in the world or universe in this localized action. The old conception

no one has or can deny and what he himself proves) that the current (and therefore the flux also) diminishes when the flux energy is used up in doing work.

He refers to one ring; the "system" consists of two rings and they must, of course, be considered together as one system, as I did. I am pleased that he admits that "some text books make wrong statements" about a circuit tending to enlarge (my Figs. 4 and 5). In saying that "sliding contacts are a nuisance" he ought to have added, to the theorist who tries to make misfits fit (and to whom they are really a blessing); starting with better laws they drop out completely as a subterfuge; sliding contacts are extremely useful in practise. Apparently in order to meet the well known exceptions to the linkage law, he says "a circuit means a closed filament of matter." I differ with him decidedly, as I have shown in the paper some extremely important differences, which every student ought to be taught, between a "circuit" (as usually considered) and the "material" of the conductor. Moreover an e. m. f. can be induced in an open circuit, a straight bar for instance. To me it seems clear that a line of flux can vanish by converting its energy into mechanical energy, hence be unlinked (in effect) without inducing an e. m. f.; but this view may not yet be generally accepted. In his thought that physicists will never adopt the line-cutting conception for that based on linkages, he is mistaken as there are prominent ones who long ago have done so; students ought to be taught both.

I am quite willing to leave it to students whether my experiments are quite "as easy to explain" by the old laws as by the proposed new ones. Surely no one but a "heretic" would ever have thought of making these experiments (which even opponents admit are interesting) and in every case the results were as predicted. I repeat here what I have often said before, that if

a teacher, who is responsible for what his students have learned, were to ask them what would happen in some of these cases, they would probably give the wrong answer or none at all. In questioning the validity of Newton's third law, I think Prof. Kennard has few if any followers. I admit having "blind dogmatic faith" in this law. His explanation of the forces in Fig. 9, are contradicted by the facts. In not accepting the longitudinal force he differs with many others, including more especially some noted French physicists, like Ampere, Mascart, Joubert, etc. When he says that Fig. 8 can be explained by the pinch effect, he shows that he has not read the paper or does not understand the pinch effect, as the observed motion of that chain is in the *reverse* direction to that which would be produced by the pinch effect. In conclusion he seems to intimate that I have not been trained "in habits of exact and consistent thought." As I have also been accused of exactly the reverse (being too exact and consistent in interpreting the old laws), I leave the verdict to the students and engineers who may read the paper.

In conclusion, now that these proposed reforms have been thoroughly discussed, some of them for years, the engineer and the student may form their own opinion as to whether they find the new or the old more useful, direct, correct, reliable and less misleading. In some respects, the choice is a matter of opinion. With liquid conductors, like in electric furnaces and in electrolysis, in which these forces have greater freedom of action than in solids, the new method will be found to be far more helpful and reliable. The open minded progressive student may find interesting departures in new fields formerly closed to us.

Those interested in the subject of this paper will find some additional matter in a note on "Magnetic Flux Around a Conductor," by Carl Hering, A. I. E. E. JOURNAL, May, 1923, p. 519.

Permeability

BY THOMAS SPOONER

Associate A. I. E. E.
Westinghouse Electric and Manufacturing Co.

INTRODUCTION

WHEN we use the term magnetic permeability we ordinarily think of it as defined by the ratio of $B/H = (\mu)$, where B is expressed in gausses and H in gilberts per centimeter. It is the ratio of the flux in a magnetic circuit produced by a given magnetizing force to the flux which would exist if there were no magnetic material present. If we are considering permeability values for inductions less than that at which maximum μ occurs the true permeability is given only when the material has been carefully demagnetized by applying gradually decreasing reversals of magnetizing force. Referring to the magnetization curve of Fig. 1 the permeability of the material at the induction P is given by the slope of the dotted straight line PO .

There are, however, other less well known types of permeability. For instance, we have the so-called differential permeability (μ_d) which may be defined as dB/dH for any point on the magnetization curve. It is the rate of change of flux with respect to magnet-

izing force. At the point P the differential permeability is the slope of the tangent drawn through this

FIG. 1—MAGNETIZATION CURVE SHOWING DIFFERENT KINDS OF PERMEABILITY

point as represented by TP . The differential permeability may be greater or less than the ordinary perme-

ability depending upon the induction at which it is taken. Another type of permeability is the reversible permeability (μ_r) of Gans'. If at any point on a hysteresis loop we apply a very small reverse magnetizing force, the induction will be slightly changed. If now, we return to the original magnetizing force the induction will return to approximately the original value with the production of a minute hysteresis loop. The change of flux with respect to magnetizing force under these conditions is termed by Gans' reversible permeability. The slope of the line through O indicates the magnitude of this type of permeability. We shall have more to say about this later.

INCREMENTAL PERMEABILITY

The type of permeability which we wish to consider here will be termed incremental permeability (μ_Δ)² and will be defined as $\Delta B / \Delta H$ where the change of B may range from the small values required by Gans' rever-

FIG. 2—MAJOR AND MINOR HYSTERESIS LOOPS SHOWING RELATION BETWEEN ORDINARY AND INCREMENTAL PERMEABILITY

sible permeability up to large values. We shall attempt to give a means of calculating its value at least approximately for any magnetic conditions regardless of the previous magnetic history of the material and for any known types of ferro-magnetic substance. A better conception of the nature of this incremental permeability may be had from Fig. 2. For any minor displaced loops superimposed on a major loop, as for instance, ab , ce , or df , the μ_Δ will be the ratio of the difference of inductions for the two tips of the minor loops to the difference of the H values for these tips. For minor loops one of whose tips coincides with one tip of the major loop the incremental permeability is represented by the slopes of the dotted lines shown at the bottom of the major loop.

The mean slopes (μ_Δ) of these minor hysteresis loops is a function of two variables, *i. e.*

1. Die Reversible Permeabilität auf der idealen Magnetisierungskurve, Richard Gans. *Annalen der Physik*. Vol. 61, No. 4, p; 379 (1920).

2. Term suggested by Mr. Yensen.

1. For a given ΔB the greater the displacement of the minor loop from its normal position the less the incremental permeability (μ_Δ).

2. For a given displacement of a minor loop the greater the ΔB the greater the incremental permeability.

There is a number of cases where a method of estimating this type of permeability is desirable. For instance, suppose we wish to insert an iron core choke in a circuit carrying direct current. The effective reactance with respect to small alternating currents in the same circuit can not be calculated even approximately from a knowledge of the permeability of the core at the induction corresponding to the known d-c. magnetizing force as may be seen from an inspection of Fig. 2. Suppose the a-c. component of current produces a displaced hysteresis loop ab . Then the effective permeability of the core is not the slope of the line oa , but the line ba , which may be very much less. In radio circuits, where we have an iron-core choke coil in the plate circuit, for instance, we have exactly this condition.

Similarly in the case of a transformer with a d-c. component of current in one of the windings a knowledge of the incremental permeability is essential if we wish to estimate the value of the a-c. magnetizing current.

If it is desired to calculate the magnitude of the skin effect due to the high-frequency flux pulsations in the laminations which make up the teeth of an induction motor, for instance, a knowledge of the incremental permeability is essential since here we have the case of displaced minor hysteresis loops superimposed on a major loop.

Again take the case of the permanent magnet of a d-c. voltmeter or magneto. According to the usual practise this magnet is magnetized with a yoke across the air gap. The magnetizing force and yoke are then removed and due to the demagnetizing effect of the poles the magnet is partially demagnetized, for instance, to a point d (Fig. 2). Now when the regular pole pieces are applied this demagnetizing effect is decreased and we have an increased flux (point f). In order to estimate this increased flux and calculate the available magnetic energy for a given type of magnet steel a knowledge of the incremental permeability is essential.

In order to devise a method of estimating this type of permeability we have principally made use of the data in two previous published articles.^{3,4} From the data of the first article we calculated the average permeability of various unsymmetrical loops and plotted these values against different variables. It was found that when plotting against pulsating amplitude a series of approximately straight lines was obtained

3. The Effect of Displaced Magnetic Pulsations on the Hysteresis Loss of Sheet Steel, L. W. Chubb and T. Spooner. *Proc. A. I. E. E.*, Vol. 34, 1915.

4. Tooth Frequency Losses in Rotating Machines, T. Spooner. *JOURNAL A. I. E. E.*, Vol. XL, Sept. 1921.

as shown by Fig. 3. The values on the curve marked B_m indicate the maximum inductions of the minor loops. The short cross lines indicate the value at which the pulsating amplitude equals one-half the pulsating flux for the major loop. Now these curves can obviously be represented by a simple formula, thus,

$$\mu_{\Delta} = a + b \times \Delta B,$$

FIG. 3—INCREMENTAL PERMEABILITY AS A FUNCTION OF B_m AND ΔB

where

a = intercept on the vertical axis,

b = slope of the line, and

ΔB = amplitude of pulsation for the minor loop.

From these data and other data largely taken from the results of the second above mentioned paper, the average curves for " a " and " b " are drawn as shown by

FIG. 4—CONSTANTS " a " AND " b " FOR INCREMENTAL PERMEABILITY EQUATION $\mu_{\Delta} = \mu_m (a + bx \Delta B)$

Fig. 4. A further examination of the various test results showed that the values of μ_{Δ} were also a function of the ordinary permeability (μ) of the material corresponding to the induction of the tip of the minor loops farthest from zero induction. The formula for incremental permeability is, therefore,

$$\mu_{\Delta} = \mu_{Bm} (a + b \times \Delta B), \text{ where}$$

μ_{Δ} = the incremental permeability or the average permeability for a displaced loop,
 μ_{Bm} = the ordinary permeability corresponding to the induction of the tip of the loop farthest from zero induction,

a and b = constants as given by Fig. 4, and

ΔB = amplitude of flux pulsation of the minor loop expressed in kilogausses.

The value of " a " when B_m equals zero is one and approaches one again for high values of B_m ; " b " approaches zero for high values of B_m .

In order to illustrate the difference between normal permeability and incremental permeability see Fig. 5. Here we have shown a normal permeability curve plotted against B_{max} and an incremental permeability curve also plotted against B_{max} where $\Delta B = 1$ kilogauss for the latter curve. As ΔB becomes smaller the difference between the two curves would increase and as ΔB becomes larger the difference would decrease.

FIG. 5—CURVES SHOWING RELATION BETWEEN ORDINARY AND INCREMENTAL PERMEABILITY ($\Delta B=1$) AS A FUNCTION OF B_m

DISCUSSION OF RESULTS

It must be understood that this method of calculating μ_{Δ} is merely an approximate empirical one and while it holds very well for most commercial ferromagnetic materials of very different properties ranging from permanent magnet steel to very high permeability vacuum iron, it is subject to considerable error for certain special types of material as will be pointed out later. If an attempt is made to use the formula for pulsating amplitudes (ΔB) much greater than one-half B_m the calculated results will in general be somewhat low. This can be seen for instance by an inspection of the $B = 3$ or $B = 5$ curves of Fig. 3. The average slope decreases at the higher pulsating amplitudes.

Now we need to give some consideration to the case of the minor loops which do not occur at the tips of the major loops. In the investigation of tooth pulsation losses in induction motors referred to above⁴, a large number of minor loops were obtained located in various

positions with a reference to the major loops of various magnitudes. So far as we could determine the average permeability for the minor loops is very largely independent of the magnitude of the major loops with which they are associated, but is chiefly determined by the amplitude and the displacement of the minor loops. A minor loop for a given amplitude and displacement will have a slightly higher μ_{Δ} if it occurs on the downward branch of a major loop above zero induction than if it occurs below zero induction, but the calculated values will in general be between the two.

Mr. Searle⁵ has published some data which may be used for checking our formulae. He applied a certain magnetizing force to his sample bringing it up to an induction, say of "a" Fig. 2. He then applied a certain demagnetizing force bringing his induction down to such a point as "o". He then reversed this demagnetizing force for two hundred times and determined his minor hysteresis loop. The μ_{Δ} or average permeability for this loop equals his apparent permeability. The following tables I and II give results deduced from his data and also gives calculated results using our method. The only difference in the various values for a given material is that a different initial magnetizing force was used in each case, the first horizontal

line corresponding to the highest magnetizing force. This means that the first horizontal line corresponds to the largest major loop.

There are some interesting points in connection with these loops.

- a. The first minor loop has 10 to 20 per cent higher permeability than the 100th loop.
- b. This change is nearly complete at the end of ten double reversals and is quite complete (within the limits of accuracy of test) at 50 double reversals.

TABLE IV
0.028" BESSEMER

B_m' Minor Loop	μ_m	μ	ΔB	ΔH	μ_{Δ}		Major Loop

7.65	1960	370	0.45	2	225	294	30.	15.45

- c. After 100 double reversals the minor loop has shifted down towards the horizontal axis to a very slight amount only (perhaps 2 or 3 per cent on the average) as shown by measuring the change in induction when going to the lower tip of the major loop.

It will be seen from these data that the low values of permeability obtained from a magnetic test sample which has been insufficiently demagnetized is simply

*Symmetrical Loop.

a case of displaced loops and if we know the displacement we may calculate the corresponding effective permeability (μ_{Δ}), which will be the test value under these conditions. The test μ_{Δ} should be compared with the normal permeability (μ) for the undisplaced loop of the same B amplitude. It will be seen that the μ_{Δ} values are always lower.

As a further check on our formulae we took Ball's

data⁶ and determined the μ_{Δ} for his test results. We then compared them with the values obtained from our formula. Table V gives the results. One tip value of the minor loop coincides with the tip value of the major loop in all cases.

Now to come to the limiting case of Gans of very small pulsating amplitudes, namely, the case of reversible permeability. This should be given by the first part of our formula, thus

$$\mu_{\Delta} = \mu_{Bm} a,$$

since ΔB and therefore b are negligible. It will be found by comparing our results with those of Gans that the values do not check well. This is due to the fact that as shown by Gans' reversible permeability is a function of the initial permeability at low and moderate inductions which varies quite considerably for various materials. For pulsating amplitudes of any appreciable magnitude when " b " becomes an important factor the results will be much more accurate since " b " is not subject to much variation for different materials (see Fig. 4), where the circle and triangle points are " b " values and the dots and crosses are " a " values. If we were to take into account the variations of the initial permeability we would have to use a different curve for each material.

Mr. Gans has given test results for four samples as shown by one of the previously mentioned articles¹. The following table VI gives his results as compared with our calculated results.

K_0 and μ_0 are respectively the initial susceptibility and initial permeability for the samples (equals the susceptibility and permeability as H approaches zero). If the reversible permeability is required accurately, it may be calculated by the following formulas due to Gans:

$$\frac{K_r}{K_0} = \frac{1}{X^2} - \frac{1}{\sin^2 X}$$

$$\frac{I}{I_{\alpha}} = \cot X - \frac{1}{X}$$

$K_r = \left(\frac{\mu_r - 1}{4\pi} \right)$ is the susceptibility for any given in-

$$\text{tensity of magnetization } I_{\alpha} = \left(\frac{(B - H)}{4\pi} \right)$$

K_r is the initial susceptibility corresponding to zero H . I_{α} is the saturation value of the intensity of magnetization.

The difficulty in using these formulas is that ordinarily we do not know either the initial susceptibility or the saturation induction since both are rather difficult to obtain experimentally.

The data of table VII were obtained from tests of various experimental alloys having a wide range of properties, and serves to show the accuracy and limitations of our formula.

The data of sample A refers to a major loop having a maximum induction of 14 kilogausses. The minor loops therefore start at a considerable distance down on the demagnetization curve of the material. For all the other samples the maximum tip of the minor loop coincides with the maximum tip of the major loop and the permeability, therefore, corresponds to the slopes of the dotted lines of Fig. 2.

Sample B is a hard chromium magnet steel, and sample C is a much softer specimen of the same sample.

Samples D, E, F and G are nickel-iron alloys supplied by Mr. Yensen. Samples E and G have very low retentivity. Sample F has a low saturation value of the order of 5 kilogausses.

Sample H is a very pure iron having a very high retentivity value.

Samples I, J and K are approximately 4 per cent silicon-iron alloys having very high maximum permeability and low hysteresis.

These samples have been selected because of their very wide variations in magnetic properties. It is seen that with very few exceptions the checks between calculated and test values are quite good, certainly good enough for any ordinary commercial calculations. When the retentivity is exceptionally low or exceptionally high (see samples E and G for low B_r values and I for high) the checks are not so good, but for materials having anything like normal B_r values regardless of the permeability whether 20,000 or 20 the calculated results check the test results very well. No check results in addition to those already presented are given for commercial electrical sheet, but in all cases that we have examined the calculated results may be relied on to within 10 or 20 per cent even in the completed apparatus.

When an air gap is present in the magnetic circuit a little different procedure is necessary in order to calculate the effective permeability. First from the known characteristics of the material calculate μ_{Δ} , then

$$\Delta H = \frac{\Delta B}{\mu_{\Delta}}. \text{ Now calculate or determine experi-}$$

mentally the gilberts per centimeter necessary to overcome the reluctance of the air gap, namely, the magnetizing force used up in the air gap to produce a change

in the iron induction of ΔB . Let this be ΔH_p . If the air gap is very short this will be approximately ΔB times the length of the gap in centimeters. Then

we have μ_Δ (actual) = $\frac{\Delta B}{\Delta H + \Delta H_p}$.

The "a" and "b" curves of Fig. 4 have not been carried below B_m values of 2 kilogausses because the effect of displacement is very small for small displacements and it is just as well or better under these conditions to use the ordinary permeability corresponding to ΔB . For values above B_m equals 18 kilogausses the hysteresis loop practically collapses and the values of μ_Δ can just as well be calculated from the ordinary magnetization curve and will be equal approximately to the differential permeability for the mean pulsating induction.

In using this method of calculating μ_Δ there are a few precautions to take, for instance, if we have the case of an iron core with a magnetizing winding carrying both alternating and direct currents, the maximum induction in the iron can not be obtained with certainty from the d-c. magnetization curve of the material and the value of the d-c. magnetizing component, but for moderate values of induction it will be higher and possibly very much higher due to two causes. In the first place the maximum magnetizing force is the arithmetical sum of the d-c. and maximum a-c. components of the magnetizing force and second the magnetic particles may be more readily oriented since they are shaken up by the a-c. magnetizing force. If the a-c. component of magnetization is sufficiently large the apparent d-c. magnetization curve will be approximately a straight line passing through the induction point corresponding to the maximum permeability and through the origin.

Above the point of maximum permeability the a-c. has little effect on the d-c. magnetization curve.

Again if the a-c. frequency is high enough or the laminations thick enough we shall have skin effects which may make the effective permeability much less than the normal d-c. value⁷ and will make μ_Δ less than that calculated by the above formula when a d-c. component of magnetizing force is present. This was evidently a large factor in the results obtained by A. W. Smith⁸, where he found even for symmetrical conditions an effective a-c. permeability of about 1/5 the d-c. value at 500 cycles. As an illustration of the use of the μ_Δ values we had occasion recently to put an autotransformer in a d-c. circuit as a choke for a small high-frequency component which was also present in the circuit. The effect of this choke could of course be determined from a knowledge of the inductance which might be calculated by the following well known formula

$$L = \frac{4 \pi N^2}{R},$$

where

$$R = \frac{l}{\mu A}$$

Now taking the permeability corresponding to the maximum induction due to the d-c. component as determined from a magnetization curve of the core material we would obtain a certain value for L . If, however, instead of using μ_{max} as determined above, we

7. Losses in Sheet Steel at Radio Frequencies, Marius Latour Institute Radio Engineers, Feb. 1919, page 61.
8. Effect of a Superimposed Constant Field upon the Alternating Current of Permeability and Energy Loss in Iron, A. W. Smith, *Physical Review*, March 1921, page 416.

use the correct value μ_Δ , the value of the inductance for the particular conditions considered is about 1/20 the value obtained by using μ_{max} .

CONCLUSIONS

We have given an approximate method of calculating

the ratio $\frac{\Delta B}{\Delta H} = (\mu_\Delta)$ usually with an error of not

greater than 10 per cent or 20 per cent for any class of ferro-magnetic materials regardless of the magnitude of ΔB and ΔH and of the previous magnetic history. The results will be more accurate if the amplitude of B is considerable. For very small values of ΔB the result may be rather unreliable. In order to calculate μ_Δ for any value of ΔB and any value of magnetic induction B_m we need simply to know the ordinary permeability (μ) of the material corresponding to B_m and the constants "a" and "b" as given by Fig. 4. It is rather surprising that this method checks as well as it does due to the fact that the curves of Fig. 4 are based on rather meager data involving only a few samples. We might have increased the accuracy by using a different "a" curve for different classes of material but this would have complicated the method and is not necessary except when considerable accuracy is required or when the ΔB values are very small. It is hoped that this simple method may find application for the solution of various electrical problems as suggested in the early part of this paper.

Discussion

E. L. Bowles: Mr. Spooner has presented some very interesting data concerning an involved and difficult subject. The analysis of circuits containing what are rather equivocally called "variable constants," is a difficult and sometimes an impossible problem. At present we are faced with a very serious situation no matter which way we turn. Variable coefficients of resistance are met with in the case of gaseous or thermionic conduction, and they are met with also in the case of circuits containing magnetic materials. In fact, even dielectrics suggest the consideration of variable coefficients. In view of these conditions, it seems that we should talk of the *Coefficients* of an electric circuit rather than the *Constants*, for after all, in developing the subject, one must overcome the handicap which results from a treatment of the electric circuit on the basis of constants.

Thus far, circuits with variable coefficients have required the use of Fourier series, Fourier integrals and integral equations. Many analyses are so involved that one loses sight of the very principle or purpose. Unless a great simplification is made in our treatment of such problems, we will have to rely almost solely upon empirical, or else cut-and-try methods. Perhaps it will be possible to develop a number of graphical solutions wherein the volt-ampere or other characteristics are used as the foundation. Graphical methods have been applied in the determination of the operating characteristics of generators and motors. To a certain limited extent, they have been applied to thermionic problems, and it is the writer's feeling that this method of attack may ultimately become a very fruitful one.

It is hard to place general confidence in Mr. Spooner's special results, since the assumptions made are likely to mislead one

rather seriously. The question of what happens in a choke coil used for radio frequency is as yet unanswerable, owing to the complexity of the conditions involved. Conclusions based on low frequency analyses can hardly hold in such cases. The reactance of an iron circuit depends not only upon the phenomenon of hysteresis but also upon the eddy current loss. The separation of these two is difficult, and in some cases it is impossible.

Another point to be brought up is the question of the inductance of a circuit containing variable coefficients. In a circuit containing a magnetic material of variable permeability, it is not possible to speak of such a thing as a constant inductance L , but rather to speak of another variable or instantaneous inductance l for the induced voltage is by fundamental concept:

$$e = -N \frac{d\phi}{dt} \times 10^{-8} \text{ volts}$$

$$= -N \frac{d\phi}{di} \frac{di}{dt} \times 10^{-8}$$

$$\text{or} \quad e = -l \frac{di}{dt} \text{ volts}$$

$$\text{where} \quad l = -N \frac{d\phi}{di} \times 10^{-8} \text{ henrys}$$

FIG. 1

If now the permeability is constant, then the derivative of flux with respect to current is constant, or:

$$L = \frac{N\Phi}{I} \times 10^{-8} \text{ henrys}$$

which is the familiar expression for inductance ordinarily used, or

$$e = -L \frac{di}{dt} \text{ volts}$$

The Research Department of the Massachusetts Institute of Technology has spent considerable time during the last three years in attempting to exactly determine the dynamical conditions existing in a magnetic circuit containing iron. Much work has been done in the development of a special bi-vibrator-quadrantal oscillograph. This idea is not new, nor was its application new in this particular case. This oscillograph consists of two vibrators facing each other, and at right angles. A beam of light striking one of the mirrors is reflected to the other, and then reflected once more, as shown in Fig. 1. In this way, a compounding of the motions of the two mirrors will produce the well known Lissajous figures in the case where the two motions are harmonic. If the deflection of one of the vibrators is made proportional to the magnetizing force, and the deflection of the

$$i_o = K_1 \frac{\omega}{R_o^2 + L^2 \omega^2} \left[B \pm \frac{R_o}{L \omega} \sqrt{B_m^2 - B^2} \right] \text{ amperes} \quad (4)$$

Or by expansion in which all terms except the first are neglected, equation (4) becomes:

$$i_o = K_2 \left[B \pm \frac{R_o}{\omega L} \sqrt{B_m^2 - B^2} \right] \text{ amperes} \quad (5)$$

From which the per cent deflection error, η_e , for a major loop is:

$$\eta_e = \frac{\frac{R_o}{\omega L} \sqrt{B_m^2 - B^2}}{B} \quad \text{numeric} \quad (6)$$

It is seen that the error is zero when $B = B_m$, and a maximum when $B = 0$, or:

$$(\eta_e)_{max} = \frac{R_o}{\omega L} \quad \text{numeric} \quad (7)$$

The area represented by the error term is of the form of an ellipse. In order that the area of the ellipse be negligible, R_o must be very low, or L very high, or both. For frequencies in the power range, L would need to be impractically large. It was attempted to make R_o small by the use of a dynatron, but difficulties were encountered which at that time, at least, could not be overcome. With no corrections for resistance, J. P. Putnam, in his Bachelor's Thesis (1921), secured some very interesting oscillograms which are shown in Figs. 5 and 6. (These were obtained with an experimental instrument as first used.) In Fig. 5, a very interesting effect is noticeable. The tips of the successive loops do not follow the magnetization curve as one ordinarily imagines. Fig. 6 shows the effect of a direct component of current in an iron core. These curves suggest points of considerable interest which can only be investigated by dynamical methods of hysteresis loss determinations.

Another method of securing a current through the flux vibrator proportional to the flux is to replace the inductance L , shown in Fig. 1, by a high resistance in series with a condenser. The difference in potential between the terminals of the condenser is:

$$v_c = 1/c \int i dt \quad \text{volts}$$

But if R_o is large, then

$$v_c = \frac{1}{R_o C} \int e dt \quad \text{volts}$$

And since the integral of voltage is flux:

$$v_c = \frac{1}{R_o C} \phi \quad \text{volts}$$

where ϕ is the instantaneous flux. The error is of the same nature as in the case of the inductance, and is expressible by:

$$(\eta_e)_{max} = \frac{1}{\omega R_o C} \quad \text{numeric}$$

The two methods mentioned are impractical as they stand, but a third method is now being worked upon, which promises to yield results which will be accurate, under the condition that the laminations making up the magnetic material under test are so thin that the effect of eddy currents is negligible.

G. H. Cole: Mr. Spooner's paper is of value to the designing engineer rather than to the mathematical physicist. It is quite probable that in the majority of design calculations involving incremental permeability, its value is simply guessed at. Fig. 5 of Mr. Spooner's paper shows that the ordinary permeability may be several times as large as the incremental permeability and hence the use of this value instead of incremental permeability may result in large errors, while Mr. Spooner's simple formula quickly gives the incremental permeability of sufficiently good accuracy for most practical purposes.

For the benefit of engineers who are accustomed to measuring electrical quantities with errors of less than a per cent, it may be well to mention that the standard method of measuring ordinary permeability of sheet steel may introduce errors, if the permeability is very high, of the same magnitude as the difference in the incremental permeability given by the Spooner formula and the test values recorded in Table VII covering a variety of materials of quite different magnetic properties. Even though the ordinary permeability may be accurately determined on specimens, the variation throughout the lot of steel from which the samples are chosen may be of the same order as those of the incremental permeability expected from the Spooner formula. This formula therefore, seems to be of sufficient accuracy for most applications and enables the designer to quickly estimate this characteristic of steel concerning which so little is generally known.

T. Spooner: With reference to the calculation of incremental permeability where the frequency is sufficiently high or the thickness of the laminations sufficiently great so that skin effect is appreciable Mr. Bowles points out that this method does not give reliable results. This is, of course, true as we have taken pains to mention in the paper. We hope to go into this aspect of the subject at a later date.

With reference to this new oscillographic arrangement mentioned by Mr. Bowles I had the pleasure a year or so ago of seeing some hysteresis loops taken with this apparatus. These loops were rather far from true hysteresis loops due to the fact that the resistivity of the secondary circuit could not be made negligible. This, of course, introduced very appreciable errors. It is to be hoped that this apparatus can be developed so that the resistance factor will be negligible since there would then be available a very valuable method of analyzing magnetic circuits under these special conditions.

It is a very easy matter to take a ring or other suitable sample of laminated steel which is provided with the necessary windings and to measure the effective permeability for various conditions of superimposed d-c. flux simply by reading the voltmeter and ammeter. We have done this in a few cases and in general have obtained fair checks with the value as calculated from the curves and formula based on ballistic results. There are some marked discrepancies, however, which perhaps Mr. Bowles' oscillographic method can explain.

Applications and Limitations of Thermocouples for Measuring Temperatures

BY IRVING B. SMITH

Member, A. I. E. E.
Leads & Northrup Co., Philadelphia, Pa.

THE increasing application of temperature measurements to central station control arises primarily from the fact that the limiting factor of safe operation is temperature rather than current or energy output. Another and closely related factor is that of efficiency. With these two influences bearing upon the management there is demanded a knowledge of temperature conditions in the boiler, the engine, the generator and the distributing system. Hence the wide range of temperatures to be measured and the varying circumstances under which they are made often place them beyond the capacity of mercurial or other expansion types of thermometers. Moreover, a permanent and continuous record of temperature may be necessary or it may be desirable to automatically control or limit the temperature of some apparatus or process. The thermocouple has definitely established itself as a convenient and precise instrument for such purposes. We wish, therefore, to consider some of the difficulties to be overcome and precautions to be taken in applying the thermocouple to such measurements.

From the viewpoint of the station engineer we may conveniently classify temperature measurements under the following heads:

1. Feed Water
2. Boiler Water
3. Economizer
4. Flue Gas
5. Superheated Steam
6. Bearings
7. Generator Windings
8. Transformer Windings
9. Cables

Before considering these applications it is desirable to refer briefly to the sources of error that may arise in making temperature measurements with the thermocouple. They may be outlined as residing in the following:

1. Thermocouple Calibration
2. Instrument Calibration
3. Thermocouple Circuit
4. Radiation Losses
5. Conduction Losses
6. Parasitic e. m. f.
7. Temperature Lag
8. Cold Junction Temperature
9. Measured Temperature Variable
10. Measured Temperature Not Representative.

I. THERMOCOUPLE CALIBRATION

A thermocouple may be in error because its original calibration was wrong or because its calibration may have changed from use. Manufacturers are accustomed to furnish thermocouples with either a table or a curve giving the relation between e. m. f. and temperature. It is not safe to employ such couples or to secure wires and make up couples without either the manufacturer's or one's own check on the calibration. This applies particularly to base metal couples but it should not be ignored even with noble metal couples. The writer received some reports recently on checks of *Pt-PtRh* couples that were apparently standard when checked by the wire manufacturer but were out 6 deg. cent. at some points when checked by the pyrometer maker. This was due in part to the use of different standard curves and in part to errors in cold junction measurements.

For temperature measurements below 320 deg. cent. it is customary to use couples of copper and constantan. They may be relied upon to remain constant to within 0.5 deg. cent. Even up to 500 deg. cent. they will be found accurate and reliable although the copper element oxidizes rapidly at such a high temperature and therefore must be renewed frequently. It is the writer's experience that electrolytic copper taken from various sources and at different times will not vary 0.05 deg. cent. when checked against the same piece of constantan. With the constantan, however, despite its name, one must use caution and not assume that any material supposedly constantan or its equivalent will have the same temperature e. m. f. relation against copper. In fact there is a sufficient variation in a single melt of constantan to demand on the part of the manufacturer that careful checks be made on all coils of wire and even at intervals along a single coil. To show to what extent a single coil of constantan may vary, ten couples were made from the same coil cutting them off in succession from the coil. They were checked with great care so that errors of checking were less than 0.05 deg. cent. The couples differed amongst themselves by 0.1 of 1 per cent at 38 deg. cent., and 0.2 of 1 per cent at 320 deg. cent. Because of the great variation in the e. m. f. of constantan when got from different sources, pyrometer manufacturers have adopted different standards of e. m. f. against copper. For example, the standards of two American makers differ 15.6 deg. cent. at 93 deg. cent. 19 deg. cent. at 200 deg. cent., and proportionately more at higher temperatures. Of course no error results from the use of any couple if the proper e. m. f. temperature relation

is known and used but it emphasizes the fact that couples should be used only with either the maker's or one's own check to insure that no error results from this source.

Up to 320 deg. cent. thermocouples may be checked against a mercurial thermometer by placing both in a well stirred oil bath keeping them close together but away from the sides or bottom of the bath. Practically the only difficulty is to obtain a reliable and accurate mercury thermometer available up to 320 deg. cent. When employing a mercurial thermometer it is necessary to avoid stem errors by immersing in the bath just up to the point where it was immersed at the time of calibrating or by applying stem corrections. Failure to do this may result in errors as great as 14 deg. cent. at 320 deg. cent. and errors proportionately great at lower temperatures (Scientific Paper No. 170 (1911) Bureau of Standards). Nearly as large errors may also result from using mercurial thermometers that have not been properly annealed. In view of these facts, the writer considers the mercurial thermometer less desirable as a standard than a thermocouple. It is found both convenient and reliable to reserve two or three copper constantan couples of about No. 22 B. & S. gage wire as standards, sending them occasionally to the Bureau of Standards for check and using them only for the purpose of checking working thermocouples. Checking one couple against another is easily and quickly accomplished. No particular precaution need be observed to avoid errors due to the cooling effect of the emergent portion of the couples. The writer immersed fine wire couples to a depth of about one half inch in a bath of mercury which was stirred and electrically heated. The couple wires were drawn down to diameters varying from 0.013 in. to 0.031 in. While the mercury was heated to 149 deg. cent. and then cooled, a continuous record was made of the differences in temperature registered by the various couples. They differed at no time by so much as 0.25 deg. cent. This difference was not increased measurably by maintaining the bath at a constant temperature and heating the extended wires to a red heat. Nor was it increased by placing the wires in ice. A similar procedure using an oil bath but immersing the couples to a depth of six inches produced like results. As indicated in Fig. 1, an oil bath had a light asbestos sheet cover $\frac{1}{2}$ in. above the oil and the thermocouple wires extended through the cover. Heating or cooling the wires was done just above the cover. It appears, therefore, that from the standpoint of cooling by conduction along the couple wires, there need be no fear of errors of any appreciable magnitude when the couple wires are of No. 22 B. & S. gage or smaller, providing the hot junction is in intimate contact with the bath. When, however, the couples are of heavy wire or are not intimately in contact with the bath, error from this source may be considerable in magnitude as well as uncertain in

amount. For example, a No. 8 B. & S. at 149 deg. cent. by immersing to a depth of six inches in oil had an apparent error of 10 deg. cent. due to conduction along the wires. By so coiling the wire that there was an amount under the oil equivalent to a depth of immersion of eighteen inches the couple showed no measurable error.

While twists and sharp bends in the couples set up strains which may be the seat of parasitic e. m. f., such disturbances are too small to be a source of trouble at temperatures no higher than those to be measured with copper-constantan couples when the wires of which the couples are made are small. The writer has taken couples of No. 22 B. & S. gage wire and twisted and

FIG. 1

bent them sharply at the point of emersion from the oil bath without introducing errors as great as 0.05 deg. cent.

In checking a thermocouple, it is sufficient, if a potentiometer method of measurement is employed, simply to twist the couple wires together, no precaution such as soldering or welding the wires being necessary. In fact, couples are often used in actual tests by merely twisting them together. While this procedure would be unsafe when measuring with a millivoltmeter, it is not conducive to error when using a potentiometer type of indicator. If, due to twisting the wires together, there results a high resistance at the joint, the only effect is to reduce the sensitivity of measurement when employing a potentiometer. As a rule the ample sensitivity will still permit of precise measurements. The writer has made accurate temperature measurements in this manner when the couple contact resistance had risen to two hundred ohms, a value so high that a millivoltmeter method of measurement would have given a totally incorrect result.

For measuring temperatures above 320 deg. cent. it is usual to employ a couple made of iron and con-

stantan. These couples are serviceable up to 1000 deg. cent. Here also care must be taken to insure that the couple is in correct calibration. A fairly large error may result from the use of iron wire not standard. In a check on a lot of iron constantan couples the iron elements were found to arrange themselves in two distinct groups, one group centering around + 0.5 deg. cent. departure from standard and the other around - 3 deg. cent. In similar manner the constantan elements grouped themselves about - 3 deg. cent. and + 5 deg. cent. These were all checked at 820 deg. cent. While the use of this material would account for an error of 8 deg. cent. at 820 deg. cent. the amount of the error at lower temperatures would be proportionately less. Iron constantan couples are very reliable in maintaining their calibration. Even though the iron is oxidized to a point of nearly opening the circuit the e. m. f. temperature relation maintains and no error is introduced if the measuring instrument is of the potentiometer type.

The life of such couples is satisfactorily long for temperatures below 1000 deg. cent. excepting however, under atmospheric conditions where oxidization is very rapid. To lengthen their life under such service conditions, they have sometimes been calorized. This materially adds to the life but changes their e. m. f. temperature relation. Twenty-four iron-constantan couples after calorizing were found to have changed by varying amounts ranging from 55 deg. cent. to 111 deg. cent. at 820 deg. cent. This variation from the original calibration was found to be wholly in the constantan. The iron wire had not changed. Making up couples using the calorized iron but new constantan, not calorized, resulted in securing the normal e. m. f. temperature relation of uncalorized couples. This, therefore, offers a means for adding to the life of iron constantan couples when they are to be used continuously in oxidizing atmospheres and at temperatures around 900 to 1000 deg. cent.

Above 1000 deg. cent. the so-called chromel alumel couple has been found serviceable. They are useful up to 1400 deg. cent. Above this temperature Pt - $PtRh$ couples must be used. As we are not, however, interested in temperatures of this magnitude, no further consideration will be given to these useful thermocouples.

II. INSTRUMENT CALIBRATION

The e. m. f. of a thermocouple is best determined by means of a potentiometer. The millivoltmeter method of measurement is for several reasons one of less precision and reliability but it has the advantage of being direct reading and of being more readily comprehended by the layman. Either type of instrument may, of course, be out of calibration and therefore should be checked occasionally. A millivoltmeter whether calibrated in millivolts or directly in temperature cannot as a rule be checked excepting in conjunc-

tion with its proper lead wires as the calibration includes the potential drop along the leads as well as the e. m. f. set up at the hot junction. On the other hand a potentiometer may be checked independently of its leads whether it reads directly in temperature or is calibrated in millivolts since the leads do not enter into the calibration. As a rule a check on the accuracy of the standard cell is all that is needed with a potentiometer to warrant one in relying upon the correctness of the instrument as a whole.

III. THERMOCOUPLE CIRCUIT

Any change in the resistance of the thermocouple circuit causes an error in a millivoltmeter type of pyrometer or thermometer proportional to such change. The circuit resistance may vary due to changes in temperature or oxidation of the leads or due to changes in the material, size or length of the leads. Oxidation of the hot junction also may greatly change the resistance of the circuit. With modern types of millivoltmeter of high resistance the error due to changes in lead temperature may be kept low but this source of error limits the length of leads which may be used.

With instruments of the potentiometer type no error results from the above sources excepting a small one arising from a change in sensitivity of the instrument due to a change in resistance of the circuit. If, for example, for some reason, perhaps oxidation of the hot junction of a couple, the resistance of the circuit has doubled, then a potentiometer capable at first of balancing to say 0.5 deg. cent. would now be of such sensitivity as to balance to 1 deg. cent. thereby introducing an uncertainty of 1 deg. cent. in the measurement from this cause. On the other hand a millivoltmeter would show an error at say 100 deg. cent. of nearly 50 deg. cent. This source of error is not readily determined with a millivoltmeter unless the whole be checked at some known temperature. Such error in a potentiometer, however, may be readily checked by simply throwing the dial somewhat off of the balance position and noticing from the deflection of the instrument to what extent the sensitivity is impaired by the unusually high circuit resistance.

On the whole the necessity of making a proper check of a millivoltmeter instrument so as to take account of changes in couple and leads as well as in the instrument is one of the chief drawbacks of this type. It demands removing the couple to some location where a definite and known temperature may be imposed and at the same time necessitates employment of the proper leads in the check to insure that no error resides in them.

IV. RADIATION LOSSES

Errors due to radiation may be positive or negative, depending upon whether the radiant energy is being transferred to or from the thermocouple. The errors are reduced by making the couple of fine wires and by not enclosing them in protecting tubes. This will be

considered in greater detail when dealing with particular measurements.

V. CONDUCTION LOSSES

In measuring temperature with a thermocouple there is, in general, an error introduced due to the fact that the wires of which the couple is composed conduct heat to or from the hot junction. With a good thermal connection between a couple and a good heat conducting solid or liquid no trouble is experienced with couples of small dimensions. Under other conditions, however, large errors may result and are often difficult of elimination or estimate. If, for example, one were to attempt the measurement of the temperature of a cylinder of baked porcelain, even a couple inserted in a hole in the porcelain would be likely to show a large error in its measurement. Heat conducted along the wires of the couple would result in cooling appreciably the temperature of the hot junction. To avoid error from this source it is usual where practical to place fine wire couples with their wires leading away from the point, the temperature of which is to be measured, along a thermally equipotential surface. This eliminates the conduction errors and permits of accurate measurement but of course is a procedure which can be followed only under special circumstances. One might naturally think that a couple of wires so fine as 0.031 in. diameter (No. 22 B. & S. gage) inserted in a fairly deep hole in a porcelain block would closely assume the temperature of the porcelain. But this is by no means true even when the block is of some good conducting material such as metal. A No. 22 gage couple was hammered

FIG. 2

flat and placed in intimate contact with a brass block at a temperature of 150 deg. cent. See Figure 2. The couple registered 16 deg. cent. low. Pressing the couple firmly against the brass block with a strip of hard fibre, *F*, Figure 2, resulted in reducing the error to 8 deg. cent. This could be reduced still more by using a plastic insulator covering the surface of the couple and the sides but there is always the danger that such a procedure will cause a change in the heat distribution and to that extent give an incorrect measurement. A similar couple with ends well twisted but not flattened and inserted to a depth of $\frac{1}{2}$ in. in a $\frac{1}{8}$ in. hole in the block registered 11 deg. cent. low. Figure 3 indicates the

arrangement. The couple made contact with the bottom of the hole. Porcelain insulating tubes slipped over the thermocouple wires failed to reduce the error below 8 deg. cent. When the hole was filled with mercury, however, the couple registered correctly to within 0.2 deg. cent. The mere contacting of a couple against a surface whose temperature is to be measured may result in large errors. A No. 22 couple bearing end on against a brass block at 150 deg. cent. registered 67 deg. cent. low. This way of applying a thermocouple is plainly not a practical method but the writer has on several occasions seen couples contacting in

FIG. 3

this manner. It is quite apparent that care must be taken if a surface temperature of a few hundred degrees *C* is to be measured to an accuracy of 10 per cent.

A couple of small dimensions embedded in the material, preferably by peening each couple wire separately into a hole in the body whose temperature is to be measured, is the best approach to ideal conditions and in many cases is a practical means of eliminating conduction errors. Under such conditions conduction errors are negligible. Small couples ranging from 0.013 in. to 0.031 in. diameter when employed in this manner showed errors of less than 0.5 deg. cent. when the extended wires were heated to a dull red and when cooled with ice.

VI. PARASITIC E. M. F.

The use of iron constantan thermocouples at high temperatures creates a region of inhomogeneity where the steepest temperature gradient exists. This becomes the seat of local e. m. f. To avoid error from this source in checking or in future use the couples should be immersed to at least an equal depth.

As stated previously, parasitic currents arising from bends and twists are small enough to neglect when using small wires and measuring temperatures of but a few hundred degrees cent.

VII. LAG

In the use of thermocouples it is sometimes required that they be protected from contact with their surroundings by lagging them. This lagging may be for the purpose of protecting them against the chemical action of gases, molten metals or liquids or it may be for the

purpose of electrically insulating them from their surroundings. The errors introduced thereby may be the result of radiation losses or simply due to the thermal resistance introduced. In the latter case the losses due to conduction are accentuated. This subject will be further considered when the various applications are taken up in detail. It might be stated, however, that under some conditions lag may be found of value in steadying the temperature readings from a varying source of heat.

VIII. COLD JUNCTION TEMPERATURE

Perhaps the one source of error most often referred to is that arising from the temperature of the cold junction of the thermocouple. It is now well understood that if a thermocouple temperature indicator is calibrated when the cold junction is at one temperature, it will not read correctly when the cold junction is at another temperature unless the instrument is so constructed as to eliminate error from this source. It is not correct, as some makers have assumed, to add to the instrument reading the excess or deficit of cold junction temperature over the calibrated value. The error from this procedure is not large when measuring temperatures of but a few hundred degrees cent. By far the best way, however, is to employ an instrument having a correct

FIG. 4

automatic cold junction compensator. There is great satisfaction in knowing that when making measurements this source of error is satisfactorily and automatically eliminated by the apparatus itself. This will be particularly appreciated by those who have taken a series of measurements, only later to make the discovery that the cold junction temperature had not been recorded or the position of the hand operated compensator was unknown. When temperatures are to be recorded an automatic cold junction compensator is essential, or otherwise interpretation of the record becomes impossible or burdensome.

IX. MEASURED TEMPERATURE VARIABLE

When the measured temperature is varying it is perhaps incorrect to attribute the error to the thermocouple but, as will be shown later, a consideration of the thermal couple design and location will offer a means for lessening any error from this cause. Cases have arisen where lag in the couple has been conducive to better results by offering an average temperature more nearly representative of the mean than would otherwise be secured. Where a recording instrument is employed it may often be so adjusted as to damp out many variations and secure a record more representative and

useful through being less subject to constant variation. And where a control mechanism is in use such lagging of the recorder or damping out of its motion may be essential for proper control.

X. MEASURED TEMPERATURE NOT REPRESENTATIVE

The measured temperature may vary in place rather than time. For example, flue gas temperatures may vary across the section of the boiler passes or down take. Here again the error is not properly an instrument error but one which may be in part, at least, eliminated by giving due consideration to the design of the couple, for example, by using a multiple couple. This will be more fully considered later.

The various applications previously enumerated will now be considered and the methods of dealing with the problems arising will be detailed.

Classification of Temperature Measurement

I. FEED WATER

The determination of feed water temperatures is usually made with a mercurial or other type of expansion thermometer. The mercury thermometer placed in a mercury or oil well is in general a sufficiently accurate method of measurement but it often entails placing the thermometer in a more or less inaccessible place and does not permit of recording such temperatures. If a record is desired or if a distant indication is deemed necessary the thermocouple will be found convenient. For this and similar applications a thermocouple has been developed which is capable of withstanding the boiler pressure and convenient to install. When supplied with an automatic cold junction compensator it leaves nothing to be desired in the way of reliability and accuracy, convenience of installation, and ability to have indications or records or both at distant points. This type of thermocouple is in design quite similar to a gas engine spark plug. As indicated in Figure 4, it is so constructed with tapered and insulated leads that the internal pressure acts to prevent rather than produce leaks. For this service no particular care need be taken to avoid errors as when once properly calibrated they should hold their calibration indefinitely. The intimacy of contact with the water whose temperature is measured insures against errors. The relatively low temperatures are within the range of copper constantan couples. There may be cases where stray e. m. f. will demand unusual care in insulating the circuit and instrument but this is a precaution which should be taken in practically any installation.

II. BOILER WATER

This problem is similar to that of determining feed water temperatures but in this case we have to contend with both high temperatures and high pressure. The same type of thermocouple plug has been found effective. The plug insulation is of mica and as stated before, the design is such as to preclude the likelihood of

leaks starting due to the pressure and temperature to which the plugs are subjected. In fact, due to improper workmanship some plugs of this type when they were first being experimentally produced did leak when first installed. The temperature and pressure to which they were subjected soon closed up the leak. It has been found practical and safe to tap such plugs directly into a boiler. There has been some discussion as to the temperature distribution throughout the tubes and drums of water tube boilers. Plugs of this type may be tapped into drums and headers and extended into tubes a distance sufficient to enable a study to be made of the relative steaming efficiency of various sections of a boiler. As in the determination of feed water temperatures no serious errors are encountered in this application.

III. ECONOMIZER

The determination of the temperature of the gases entering and leaving economizers has been made by means of thermocouples arranged in series and so disposed as to secure an approximation to the average temperature of the gas. In this case the various cold junctions are brought out to a convenient point where a compensator is applied.

When such couples are placed both before and after the economizer a double curve drawing recorder may be employed indicating at each instant the temperature of the entering gas, the temperature of the exit gas and the drop in temperature through the economizer.

IV. FLUE GAS

A continuous record of flue gas temperatures may be required or it may be desired to control some other element of operation automatically in terms of flue gas temperature. The thermocouple controller recorder offers a means of accomplishing either or both results.

Kreisinger in Bulletin No. 145 of the Bureau of Mines calls attention to the fact that the major error in the determination of flue gas temperatures is that due to the radiation from the couple to its cooler surroundings unless precautions are taken to prevent such error. He states that under some conditions the error may amount to several hundred degrees in some passes of the boiler. Even in the down take an error of 25 deg. cent. may result from this cause.

In the last pass of the boiler or in the down take the error is always in a direction indicating temperatures lower than actual, owing to the fact that the tubes in the last pass are at a much lower temperature than the gases. For this reason the couple radiates to the tubes and is therefore lowered in temperature. Kreisinger pertinently calls attention to two points: first, that the degree of accuracy of gas temperature measurements depends more upon the judgment of the user of the instrument than upon its correct calibration and second, because an instrument is correctly calibrated, the readings are too often assumed to accurately indicate the temperature of the gas.

The important point to note in gas temperature measurements is that the larger the diameter of the couple or its protecting tube the greater the radiation error will be. While it is usually assumed that a heavy couple or a heavy protecting tube markedly lowers the couple temperature by reason of conduction along the wires or protecting tube such is not generally the case. The conduction error can be made small. The real source of error lies in the fact that a large diameter couple offers a large surface for gain or loss of heat by radiation. With a couple projecting into the hot gases a distance of eighteen inches, conduction error may be ignored. Hence a properly constructed couple for gas measurements should be placed in a substantial steel tube for mechanical strength but the hot junction of the couple should be exposed for a distance of perhaps

FIG. 5

six inches. The couple wires should be unprotected for this distance and should be not larger than No. 22 B & S. gage. With the low temperature of flue gases 200 to 250 deg. cent. and with a couple constructed as above outlined the gas temperature should be measurable to an accuracy of 3 to 5 deg. cent.

In the last pass of a boiler where the temperature of the gas may be 650 deg. cent. to 750 deg. cent. this type of couple should give a reading not more than 25 deg. cent. low. Experience seems to indicate that for the latter measurement a correction approximating 3 per cent will leave only a small outstanding error and for temperatures in the down take a correction of about 1 per cent will allow for the lowering of temperature due to radiation.

In some tests made for the writer for the purpose of determining the error in flue gas measurements due to radiation, screens or baffles were so located and constructed as to shield the couple from radiation to the boiler tubes. The arrangement is illustrated in Fig. 5. The rod A could quickly slide the baffles away from the couple. They could be quickly withdrawn and replaced without disturbing any part of the couple and without loss of time. When readings were made in rapid succession both with and without the baffles, differences of temperature of not over 1 deg. cent. resulted. In this case the couples were of No. 22 gage wire. While this method is a satisfactory means of measuring gas temperature at a point in the flue it does not insure that the measured temperature is a representative one. For this reason multiple couples have been used to secure an average in the same manner as in averaging the temperature of economizer gases.

V. SUPERHEATED STEAM

The thermocouple because of its rapid response to changes in temperature, has found an unexpected application in connection with the measurement of temperature of superheated steam. If water is carried along with the steam and strikes the thermocouple it lowers its temperature suddenly. A continuous record of the thermocouple temperature, therefore, shows sudden breaks, the cause of which is readily recognized. The application to this service was primarily for the purpose of determining the degree of superheat in making acceptance tests of superheaters. It proved very useful in this respect in that it was immediately responsive to any changes due to change in load and was free from suspicion of error due to lead conduction.

For this service the plug type couple will be found useful. Experience, however, shows that its construction must be carefully attended to in order that it may have sufficient rigidity to withstand the rather high pressure due to the velocity of the steam and the impact of the water.

VI. BEARINGS

Thermocouples embedded in bearings operate under conditions that insure reliable measurements providing care is taken to secure proper electrical insulation in order that stray currents may not produce errors.

The couple should be set in a hole of such depth that the hot junction is near the running surface and should be made of small wires, otherwise conduction along the wires may result in indicating too low a temperature. Couples constructed and installed as indicated in Fig. 6. have been suggested although the writer cannot say whether they have been tried out.

FIG. 6

This construction grounds the thermocouple since the copper sheath is one element of the couple. Perhaps a better construction would be to use silver for a sheath for only about one inch of length the balance being made of porcelain or light wall german silver. In this case the couple can be made of fine wire and insulated from the sheath.

It is practical to keep not only a continuous record of bearing temperatures but to have the recorder furnish a light or bell signal if the temperature rises above a safe limit.

VII. GENERATOR WINDINGS

After a careful analysis of the design of a machine has indicated the probable hottest region, there remains the problem of so locating the couple as to

enable the temperature of the *copper* at this point to be determined.

In service, the couple has to be placed outside the insulation and therefore a correction is necessary for the temperature drop through the insulation. Standard corrections for this drop have been adopted in the Standardization rules of the A. I. E. E.

In a shop test constantan wires can be substituted for some of the small strands in the armature conductors and these constantan leads welded to the armature copper at the hot spots. A potentiometer connected between the constantan lead at the neutral point, if grounded, and the neutral copper will permit determination of the copper temperature. If at the same time additional copper constantan couples are placed outside the copper insulation adjacent to the first couples, simultaneous measurements will give the correction for the latter couples when used in service.

After the test the leads of the inside couple can be cut off.

Thermocouples installed in generators are subject to strong a-c. fields hence they should be so designed as to prevent heating due to eddy currents.

Thermocouples used in generators are always grounded as a protection to the operator but of course only one ground is permissible since the difference in potential between two grounded points may be large in comparison with e. m. f. generated in the couple. Couples should not have common return leads as this gives rise to trouble and also makes it more difficult to locate trouble. Furthermore, trouble in any one couple effects the whole system and not simply its own circuit.

It is almost unnecessary to point out that the leads should be individually insulated with good rubber. The fact that the e. m. f. of a thermocouple is but a few millivolts may lead to the inference that a low insulation is sufficient.

VIII. TRANSFORMER WINDINGS

Thermocouples have not been used to any great extent in this country for measuring the temperature of transformer windings. The resistance thermometer has the advantage that it may be placed in an a-c bridge and insulated by means of a special insulating transformer. This is the arrangement used by the General Electric Co.

Large transformers are usually of higher voltage than generators and consequently the insulation problem is more difficult. Even if the "hot spot" could be reached, it would not be safe from the standpoint of life hazard to use underground thermocouples, and it would cause dangerous stresses in the insulation to run grounded thermocouples into the windings in the ordinary manner.

The Westinghouse Company employs an "artificial

hot spot" located in the oil of the transformer and supplied with current from an auxiliary transformer. In this "artificial hot spot" it is safe to place a thermocouple or any convenient type of temperature detector.

Very many high-voltage transformers have one winding connected in Y with the neutral solidly grounded. Accordingly it is possible to place thermocouple leads in the main winding with the instrument connected at the neutral point. This method is now being investigated by one of the transformer manufacturers.

IX. CABLES

In the last year or two the thermocouple has been used extensively for temperature measurement in cable systems. The thermocouple is valuable in this work because of its extreme simplicity and robustness.

Where it is possible to solder the couples to the lead sheath of a cable before drawing in, the problem is rather simple. The errors to be avoided are those due to stray e. m. fs. leaking on to the leads, and due to e. m. fs. produced by electrolytic action on the thermocouple leads. The ducts are usually very wet and excellent insulation is required to avoid the errors mentioned.

Most of the measurements have to be made in empty ducts as it is not possible to pull a couple for any great distance into a duct occupied by a cable. However, thermocouples can be pulled into occupied ducts up to limited distances, but there is considerable uncertainty in the measurements as it is quite impossible to tell whether the couple is in contact with the sheath, the duct wall or neither.

Whether the couples are pulled into empty or occupied ducts it is necessary to guard against conduction along the leads and it has been found advantageous to place a small mass at the hot junction in order to reduce conduction errors. This makes it necessary to leave the couple at each point to be measured for a considerable length of time (15 minutes to $\frac{1}{2}$ hour) to allow the mass to assume the local temperature.

Of course the results are affected by radiation from and to the duct walls, but this error is probably small and usually in the direction to show a temperature more nearly that of the cables in adjacent ducts.

Long leads are used with thermocouples for cable measurements and these leads are subjected to varying temperatures along their length. The temperature of leads may be above or below the junction temperature but is not very different. It is necessary to select the lead wire in order to avoid errors due to parasitic e. m. fs. but it has not been difficult to obtain lead wire which is apparently very satisfactory.

The writer is indebted to Mr. I. M. Stein of the Leeds & Northrup Company for the substance of the remarks pertaining to generators, transformers and cables.

Discussion

E. D. Tanzer: Not so long ago, a thermocouple was solely a physicist's instrument. At the present time, however, it has a wide field of application among the operating companies. At least, we of the Philadelphia Electric Company, during the past three years have used it extensively in field determinations of the operating temperatures of cable duct lines, cable sheaths and transformer manholes, as well as in research problems pertaining to the operation of an extensive underground cable system.

Mr. Smith has defined very nicely some of the limitations inherent in the use of various types of couples in the field. We have experienced in our own investigations, some of these same factors, and accordingly I believe that it may be of interest to show some ways in which we have found the thermocouple particularly useful in the investigation of temperatures in our underground system.

In measuring temperatures in duct lines, carrying several cables, it is obviously impossible to get the thermocouple into a duct occupied by a cable. The only thing that we can do is to devise a means of readily locating a couple along an adjacent empty duct.

In the device utilized for this purpose a mandril carries the thermocouple. In the center of this mandril, the thermocouple junction, imbedded in a small copper block, is protected so far as possible from any mechanical injury that might result from pulling the mandril through a duct. The first of these devices made up to investigate a duct run of about 400 feet length, was made with these mandrils spaced at approximately 50 foot intervals. The little block of copper in which the couple junction is mounted, is for the purpose of providing a small amount of thermal capacity just at that particular point and so obviate the possibility of heat radiation or conduction away from the couple junction itself since this would mitigate against the accuracy of its indication.

In one particular duct line in which a large number of measurements were made we had a duct length of about 400 feet badly congested with cables. Accordingly, a great deal of heat was to be radiated and the operating temperatures were rapidly becoming large. Thermocouples made possible the exact determination of the existing temperature within this duct run and so gave the load ing that could be used to advantage for the cables involved. The configuration of the duct run was such as to cause difficulty in determining temperatures at midlength locations. The leads from each of the 50-ft. spaced couples were all brought back to the one location enabling the operator to read the temperatures along the duct run with a minimum of effort.

Couples have also been used to determine the location of a leak beneath the street level in a steam service main. In this case steam was present in adjacent manholes but the exact location of the leak was not readily determinable from the surface of the street by ordinary methods. However, by checker-boarding the surface of the pavement and locating a couple at the center of each one of these squares, the temperatures attained by the couples served to indicate the particular point in the steam main which was giving trouble, to within a distance of approximately 3 ft.

I believe, therefore, that in the future, there will be more, of what I might call "out of the ordinary," applications of thermocouples to the problems of the operating companies. Accordingly, Mr. Smith's paper is very timely as it discusses some of the things which we cannot expect thermocouples to do. For instance, although the couple, by itself, is very accurate, yet it may be so mounted as to nullify a portion, or even a large part, of its accuracy. Particular attention, therefore, must be devoted to not only the couple itself, but to the mounting with which the couple is to be used.

G. H. Cole: Thermocouples, because of their simplicity are frequently used under conditions which have been given

little thought. For example, even with somewhat more thermocouple experience than the average engineer, it is improbable that I would have hesitated about measuring the temperature of a brass block by putting a thermocouple junction at the bottom of a small hole $\frac{1}{2}$ in. deep, as shown in Fig. 3 of Mr. Smith's paper, unless very good results were desired. Yet this procedure resulted in nearly as great a difference in the temperature desired and that read as between the mean temperature of May and December in New York City.

While it is well known that the temperature drop at surfaces of solids through which heat flows is relatively large, as for example at the junction of bricks in a furnace wall, Mr. Smith's paper has been of value in calling attention to the need for using this knowledge in thermocouple applications.

Due to the numerous surfaces to be crossed by heat flowing across a laminated transformer core, the thermal drop may 50 to 100 times greater in this direction than perpendicularly to it for the same distance in one lamination. The foregoing indicates the importance of making intimate contact with the surface whose temperature is to be measured.

I would like to ask Mr. Smith if surface drop and conduction errors can be largely eliminated by having the two thermocouple wires make contact with the body to be measured at different points.

R. P. Brown: Mr. Smith, in his paper, makes the following statements:

"Any change in the resistance of the thermocouple circuit causes an error in a millivoltmeter type of pyrometer or thermometer proportional to such change." He further states:

"With instruments of the potentiometer type, no error results from the above sources excepting a small one arising from change in sensitivity of the instrument due to a change in resistance of the circuit"—which he explains, with doubling the resistance of the circuit, might cause an error of 1 deg. cent. Mr. Smith further adds:

"On the other hand, a millivoltmeter would show an error at say 100 deg. cent. of nearly 50 deg. cent. and that this source of error is not readily determined with a millivoltmeter unless the whole be checked at some known temperature."

In making a comparison of the errors encountered in using a millivoltmeter pyrometer as compared to a potentiometer pyrometer, under conditions wherein a thermocouple circuit resistance is doubled, it is, of course, necessary to compare on the basis of the same thermocouple circuit conditions for each meter.

In the case of a millivoltmeter pyrometer normally of about 600 ohms resistance and used with a thermocouple circuit of, say, one ohm resistance, it would be necessary for the thermocouple circuit to be increased to 600 ohms in order to halve the deflection of the millivoltmeter pyrometer.

For comparison,—in the case of a potentiometer pyrometer, the same thermocouple circuit conditions must necessarily exist. In other words, the same change from one ohm to 600 ohms must take place. Mr. Smith, in his paper, states that an uncertainty of $\frac{1}{2}$ deg. cent. normally exists. He then states that by reason of the circuit resistance being doubled, the uncertainty in reading becomes 1 deg. cent. instead of $\frac{1}{2}$ deg. cent. This is not possible under the conditions encountered in the usual potentiometer furnished for such measurements. The slide wire resistance of such a potentiometer is normally approximately 30 ohms and the galvanometer resistance is approximately 20 ohms. It is therefore apparent that a change in the resistance from one ohm to 600 ohms in the couple circuit would far more than double the uncertainty existing in measuring with a potentiometer. Since the total circuit resistance increases from approximately 51 ohms to 651 ohms, it is evident that the uncertainty of measurement must increase in ratio of the resistance. In other words, the uncertainty of the balance will then be 13 times as great as originally, thus amounting to approximately $6\frac{1}{2}$ deg. cent., instead of 1 deg. cent. claimed

by Mr. Smith. From this it is apparent that the comparison as made is incorrect, in that the same condition of thermocouple circuits have not been applied in making the comparison.

The only condition under which the comparison as stated would be substantially correct, is to assume that the thermocouple circuit, as referred to by Mr. Smith, applies only to the external circuit, including the thermocouple and its lead wires.

The average millivoltmeter pyrometer of today, put out by the majority of manufacturers, has an internal resistance of some 600 ohms. I have seen an instrument made by one of our competitors having a resistance of 1200 ohms and we frequently build instruments of this resistance ourselves, but to take an average condition, we can assume 600 ohms for the instrument.

A thermocouple most commonly used, 36 in. long, with 15 ft. of extension leads to convey the cold junction from the thermocouple to the instrument, has a resistance of $\frac{3}{4}$ of an ohm. Lengthening the extension leads from 15 to 30 ft. and increasing the thermocouple from 3 to 6 ft. long, would double the resistance of this circuit and would produce an error of only 1.3 deg. cent. in the readings of an instrument graduated, for example, to 1000 deg. cent. This is equivalent to only 0.13 of 1 per cent error (instead of nearly 50 per cent claimed by Mr. Smith.)

It is misleading to have a statement appear broadly implying that a millivoltmeter pyrometer would show an error at, say, 100 deg. cent. of nearly 50 deg. cent. on account of doubling the thermocouple circuit resistance.

The variation in temperature of the lead wires, referred to by Mr. Smith, will also produce exceedingly small errors in a modern millivoltmeter pyrometer. Assuming a length of lead wire of 100 ft., the change in resistance due to a change in temperature of 100 deg. cent. will amount to 0.1 ohm in a circuit of 600 ohms, or about 0.02 per cent. On a pyrometer reading to 1000 deg. cent. the error would amount to only 0.2 deg. cent. It is quite evident, therefore, that errors in a high resistance millivoltmeter, due to lead wire changes in temperature, are immaterial.

The only remaining possible cause for change in resistance in a millivoltmeter pyrometer, is the change produced by oxidation of the thermocouple. Claim is made that oxidation of the thermocouple results in an increase of thermocouple resistance, thus affecting the millivoltmeter pyrometer and not the potentiometer. The truth of the matter is that resistance errors due to oxidation are exceedingly small. Before the deterioration of a thermocouple can be carried to such an extent that the resistance errors are appreciable, the e.m.f. of a thermocouple changes so badly as to render the thermocouple useless for measurements either with a potentiometer or a millivoltmeter.

When we compare the relative merits of the millivoltmeter and potentiometer for temperature measurements, let us not take for comparison a type of millivoltmeter which is not produced and compare it with a standard potentiometer.

I recognize the valuable features in both instruments—the millivoltmeter for its simplicity, the ease with which an unskilled operator can use it, its absence from standard cells, dry batteries and slide wires required in the potentiometer.

In the potentiometer I recognize its valuable feature in the entire absence, for practical purposes, of any errors due to changes in circuit resistance, and its value for extremely accurate measurements of temperature. Both types of instruments have their field and both have many valuable features.

I. B. Smith: The calculations made by Mr. Brown and myself may be carried out in a variety of ways. It seems hardly worth while, however, to go into details since Mr. Brown and myself appear to be in agreement as evidenced by his last remark, that one valuable feature of the potentiometer is "the entire absence for practical purposes, of any errors due to changes in circuit resistance."

The Measurement of Power in Polyphase Circuits*

BY CHARLES FORTESCUE

Fellow, A. I. E. E.

Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa.

Review of the Subject.—The object of this paper is to point out that the existing methods of measuring power when applied to unbalanced three-phase systems are not equitable for symmetrical polyphase machinery. On the other hand, unsymmetrical loads on polyphase systems are not sufficiently penalized for the trouble which they create in the system.

It is first of all shown that a symmetrical generator cannot deliver power except through the balanced components of current. The unbalanced currents are capable of resolution into two balanced systems of currents, one of which is of the same phase sequence as the generator e. m. f., and the other component is of reversed or negative phase sequence. The generator cannot deliver power through the medium of this latter component of the currents, because the instantaneous product of the generated voltage and these currents in the three phases is always zero. However, the volt-ampere product per phase is of great significance, because it is a measure of the effect of the current unbalance on the system.

The generator therefore delivers power only through the medium of the positive phase sequence currents. Any power that appears in the system through the negative phase sequence currents is positive phase sequence power which has been supplied by the generator and degraded through unbalanced loads and fed back to the system in the form of negative phase sequence power. This power is always additional loss in all rotating machines on the system, and with the present method of charging, the consumer having symmetrical machines is charged with this additional power, which serves him no useful purpose but reduces the output of his machine and decreases his load power factor.

In the paper it is proposed that the positive phase sequence power output only be measured, and the power charges be made on the basis of this measurement. It is further proposed that the unbalanced $k\text{-va.}$, which is the product of the positive sequence voltage and the negative sequence current be measured either by means of a negative sequence ammeter, indicating or recording, or a $k\text{-va.}$ meter, and a charge made for the amount of unbalance. The user of symmetrical polyphase rotating machinery should then be given a lower rate, based on the estimated cost of unbalance, and the consumer having unbalanced loads should be charged directly for the amount of unbalance he creates, or else should have his positive phase sequence power rate increased, based upon the estimated cost of unbalance.

It is pointed out that the unbalanced $k\text{-va.}$ is a factor of the same order of importance as reactive $k\text{-va.}$ and in any system subject to unbalanced conditions this factor should be considered and the unbalanced factor, as well as the power factor, should be measured. The unbalanced factor is the ratio of the negative phase sequence $k\text{-va.}$ and the positive phase sequence $k\text{-va.}$, the former being obtained by taking the product of the positive phase sequence voltage and the negative phase sequence current.

Devices for measuring these quantities are being developed and the outfit for making these measurements will be no more complicated than the present existing measurement devices. In fact the tendency is towards greater simplicity.

In presenting this subject the author has no intention of suggesting how rates should be made, but merely wishes to point out what factors enter into the question of equitable rates when the polyphase system is subject to unbalance.

GENERATORS

FOR the purpose of this discussion, it will be sufficient to consider symmetrically wound machines.

Such machines when excited by a direct-current machine, give balanced three-phase voltages at their terminals of sine wave form. If currents are supplied from these terminals to a symmetrical load, they will be in balanced three-phase relation to one another, and the sequence of the maxima of the current waves will be the same as that of the generated e. m. f. waves. Generators are usually built with the field the rotating member; to avoid confusion we shall refer to this member as the rotor and the rotor field will in general be the main field of the machine, although as we shall see later, the main field is, in reality, a field set up by the resultant of the m. m. fs. of both stator and rotor.

A symmetrical system of currents flowing in the stator winding produces a resultant synchronously rotating m. m. f. which in the case of balanced currents having the same sequence of phases as the generated e. m. fs. will rotate in the same sense as the main field, and its phase position with respect to the main field will depend upon the time phase of current with respect to the e. m. f. Where the relation between m. m. f. and field is linear, the former may be resolved into two

components at right angles with each other, and the field that would be produced by these m. m. fs. may be compounded with the field produced by the exciter currents in the stator to give the actual field of the machine under load. Since the e. m. fs. produced by the components will be proportional to them, we may consider these components in terms of the e. m. fs. they produce in the stator winding and compound these instead. Thus, in each phase an e. m. f. will be produced by the resultant magnetomotive force due to the symmetrical currents flowing in the stator windings and will lead it in time phase by one quarter of a cycle. In addition to this e. m. f., there will be a resistance drop due to the current in its windings. A complete theoretical discussion of these problems is given in the appendix. It is shown there that if the resistance drop which is negligible is ignored, the increase in exciting current required to maintain a given e. m. f. is proportional to the wattless current, and the phase angle of the rotor and armature adjust themselves, so that there is equilibrium of induced voltages. In other words, the presence of wattless lagging current in the winding necessitates a proportional increase in the exciting current. This entails larger conductors in the exciting winding and larger parts for the complete machine. The effect of saturation is not so important as might be supposed; for since the field itself does not

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 14-17, 1923.

change in value during a cycle, the value of the average mutual and self inductance will not be affected during a cycle, but will depend upon the average degree of saturation present. In most machines this does not vary much from no-load to full-load on account of the long air gaps.

Let us suppose the generator to be provided with a winding on the rotor of similar character to the stator winding, but short-circuited on itself. It will be quite obvious that the various component fields discussed above, since they are stationary with regard to the rotor, will have no inductive influence on this winding and that, therefore, so long as the machine is rotating at uniform speed, and the currents in the winding of the stator are symmetrical three-phase of the same sequence as the terminal e. m. fs., no current will flow in this winding. Let us now consider the effect of a system of balanced three-phase current, the sequence of whose maxima is opposite to that of the generated e. m. fs., that is to say, the maxima of the currents in phase *A. B. C.* instead of following in time the order *A* leading *B* and *B* leading *C*, will instead follow the order *C* leading *B* and *B* leading *A*. It will be evident that the sequence of these currents will correspond with the normal sequence of currents for the same machine with the direction of rotation reversed, consequently following the same general reasoning for the case of normal sequence given above, this system of currents will set up a m. m. f. rotating synchronously in the opposite direction to the m. m. f. of the exciting current of the rotor. This m. m. f. will, therefore, rotate relatively to the distributed winding on the rotor at double synchronous speed and the field it will tend to produce will set up double frequency-balanced polyphase currents, which will in turn set up a m. m. f. opposing that due to the stator currents.

The field actually produced will be the resultant of these two opposing m. m. fs., and will be such as to produce e. m. fs. of sufficient value to overcome the impedance of the rotor winding due to its resistance and leakage reactances. We have here an action similar to that of a short-circuited transformer, the difference being that there is in addition a transformation of frequency that is always accompanied by a transformation of mechanical power into electrical power. In this particular case, the transformation of mechanical power into electrical is such that one-half the secondary losses are directly supplied through rotation by the prime mover. The e. m. f. at the generator terminals required to force this current through the stator windings will be determined by an impedance which will be similar to the short-circuited impedance of a transformer. Similarly, the relation between the double-frequency rotor current and the stator current will be similar to that between the secondary and primary currents of short-circuited transformers. For practical purposes, we may say that the ampere-turns of stator and rotor winding will be equal. These relations

are independent of the actions accompanying the flow of balanced currents of normal frequency in the windings.

It will now be evident that the presence of current of opposite phase sequence in the generator e. m. f. requires something in the generator which was not necessary before, that is, damper capacity, and this is a further requirement in addition to the additional capacity required in the stator winding as a result of the current.

The product of the negative phase sequence current and the normal terminal voltage is a measure of the amount of phase conversion taking place in the generator and the presence of the negative phase sequence current requires this phase converting capacity in the machine. The mean heating in the stator will be proportional to the sum of the squares of the positive phase sequence current and the negative phase sequence current; and the heating in the rotor will be proportional to the sum of the squares of the exciting current and the double-frequency current if they have a common winding.

It has been shown elsewhere and the solution has been repeated in the appendix that the operation of a generator depends upon two fundamental impedances, namely, the impedance to the normal balanced current or positive phase sequence impedance, and the impedance to the negative phase sequence current, the action of which we have just discussed; this latter is the negative phase sequence impedance.

In this discussion we are leaving entirely out of consideration currents flowing through the winding by way of the neutral of the three-phase winding. These currents while important in questions of inductive interference are of little importance in commercial power circuits. It seems hardly necessary to say that a solution of any circuit condition may be obtained without the use of positive and negative sequence currents and impedances by using self and mutual impedances. These impedances are, however, difficult to evaluate and are not the natural constants of the machine.

A discussion of the equations of a generator using self and mutual impedances and the derivation of their relation to the positive and negative phase sequence impedance will be found in the appendix. This method of solution might be regarded as the single-phase method of treating a polyphase problem, each phase being considered as a single-phase branch circuit related to the other circuits through mutual impedance.

In the symmetrical coordinate method, the symmetrical polyphase component system are the units, and these have definite impedances and are independent of each other in a symmetrical machine. This method, therefore, leads to considerable simplification. It is interesting to note that a similar relation holds between the phase impedances and the positive and negative sequence impedance, as exists

between the phase currents and the positive and negative sequence components of current.

We are not concerned, however, with the mere solution of the three-phase circuit, but what we desire is a measure of the requirements of the machine.

(1) How much true power it must carry—kw. capacity.

(2) How much reactive power it must supply—exciter capacity, field copper, additional stator copper.

(3) How much unbalanced kv-a. it must supply—its phase-converter capacity—damper windings on rotor—additional copper on stator.

The first two requirements are well known, the first being determined by the demand for power current or active component of current, the second being determined by the demand for magnetic energy which is furnished by the reactive component of current. The third requirement is determined by the magnitude of current unbalance, and is measured by a balanced system of currents, the sequence of the maxima of whose phases is the reverse of that of the generated voltage.

If we take I_1 for the total current due to the first two, then if I_p, I_q be the two components of power current and wattless current respectively, $I_1^2 = I_p^2 + I_q^2$. If I_2 be the third current, which measures the magnitude of the unbalanced flow, the total average heating in the stator alone will be determined by $I_1^2 + I_2^2 = I_p^2 + I_q^2 + I_2^2$, so that in its relation to the generator capacity, I_2^2 is a factor of the same order as I_q^2 , and the three quantities as regards the average heating are independent of one another, and the necessity for supplying I_2 calls for additional copper in the stator winding as well as the addition of a suitable damper winding. To sum up: The character of a generator is such that it has three functions:

(a) To deliver true or active power.

(b) To deliver reactive power or supply magnetic energy.

(c) To maintain balance at its terminals (phase converter capacity.)

The quantities that are measures of these three characteristics combine as far as average total heating is concerned as if they were three vectors in space mutually at right angles to one another.

In the preceding paragraphs, we have concerned ourselves only with the average heating, due to the presence of unbalance currents. We have shown that a machine subjected to such operating condition must have damper capacity and additional copper in the stator; but this is not the whole story, the effect of unbalance is to cause unequal dissipation of energy in the three phases, as a result any phase may have to withstand a loss several times the average loss according to the average loss expression given in one of the preceding paragraphs. Since the phase of the negative phase sequence component current is not definitely fixed, any one of the three phases may have to stand this high loss.

In a single-phase machine, the unbalance is definite and may be provided for, but in a three-phase machine, each winding must be designed for the maximum possible loss it may incur under unbalanced loads.

It appears to be a reasonable deduction that the simplest system and the most fundamental one in considering a rotating machine, is one in which the reactions in the magnetic circuit will appear in terms of fields of the same character as that set up by the rotor. We see that balanced currents flowing in the stator will set up a field of this character which may be combined simply with similar fields set up by other balanced systems of currents. The balanced systems of currents in the stator setting up these component fields will differ from one another in magnitude, phase-sequence and frequency. Any particular component fields may be the resultant of two balanced systems of current, one of which flows in the stator winding and the other in the rotor. A balanced system of currents which produces a m. m. f. rotating in the same direction as the main field is termed a positive phase-sequence system. A system of balanced currents flowing in the stator producing a field rotating in the opposite sense is termed negative phase sequence. It is convenient to refer all the quantities to one phase "A" which is termed the principal phase.

In dealing with the generator in these terms, we are considering the field as resolved into component fields of exactly the same character as that set up in the field magnetic circuit by the exciter. In the complete theory the field may be compounded of a number of fields of different numbers of poles rotating at different multiples or submultiples of the speed of the main field. Rotating positively or negatively each field is associated with a symmetrical system of currents in both rotor and stator, each having a definite frequency depending on the speed of rotation of the field and a definite phase sequence depending on the direction of rotation.

The instantaneous value of the field set up by a symmetrical system of currents of other than sine wave form in a symmetrically wound generator may be expressed in the form of a Fourier series consisting of only odd harmonics of the fundamental, the electric angle for a complete pole pitch being 2π . In the three-phase symmetrical generator, there may be present in the field form, due to the symmetrical currents, the 5th, 7th, 11th, 13th, etc., harmonics of which the 5th, 11th, 17th, etc. will be fields rotating in the negative direction while the 7th, 13th, 19th will be positively rotating fields.¹ On account of the counter m. m. fs.

1. The reason of this may be explained very simply as follows: If we take the wave form of say phase A and displace it through the angle $\frac{2\pi}{3}$ we obtain the wave form of phase B for a symmetrical machine. For the r th harmonic which has $1/r$ th the wave length, this displacement corresponds to the harmonic

due to currents set up in the damper winding and in the pole faces, these harmonic fields are largely damped out. The harmonic fields due to the flow of symmetrical positive phase-sequence currents of fundamental frequency do not produce harmonic e. m. fs. in the stator, but the e. m. fs. produced are all of fundamental frequency and of symmetrical positive phase sequence. The field forms so produced are of the nature of sub-multiple rotating fields, having numbers of poles related to the main poles in the inverse ratio of the relative rotational speeds. Their values are small, due to the counter reactions set up by the induced currents in the rotor.

The fields set up by the flow of negative sequence current of fundamental frequency in the stator are of similar character, but the direction of rotation is reversed, consequently, all these fields are opposed by those of the currents set up in the damper windings. All the e. m. f. set up in the stator is used up in overcoming the resistance and the internal reactance of its windings and in addition a certain amount of mechanical power is required to produce a portion of this e. m. f. which is dissipated in the form of $I^2 R$ in the rotor windings. The e. m. fs. set up in the stator are all dissipative and reactive e. m. fs.

A symmetrical rotating machine driven below synchronous speed is incapable of delivering power when excited in the primary alone; an additional exciting agent in the secondary circuit is required. Any mechanical power necessary to drive such a machine is used up in heat losses in the windings. The above includes machines driven in a negative direction at any

angle $= \frac{2 r \pi}{3}$. If r is a multiple of 3, we see that the angle

$-\frac{2 r \pi}{3}$ is always a multiple of 2π or a complete electrical

revolution, so that in a three-phase machine, all harmonics which are multiples of 3 give voltages in phases $A B C$ in phase with one another. The two groups of numbers $(6n - 1)$ obtained by giving n all integral values from 1 to infinity give all the odd integers from 5 to infinity, except the multiples of 3. If we take r equal to $(6n - 1)$ this group of harmonics will be displaced by the angle $-4n\pi + \frac{2\pi}{3}$ or what is the same thing

by the angle $\frac{2\pi}{3}$ that is to say phase B will be advanced by this

angle; similarly if r is taken equal to $(6n + 1)$ the angular displacement for the harmonic will be $-\frac{2\pi}{3}$, that is, this group

of harmonics will be displaced in phase B by the angle $-\frac{2\pi}{3}$. Hence the first group will be positive phase sequence,

while the second will be negative phase sequence. In $(6n - 1)$ giving all integral values, we obtain the harmonic group 5, 11, 17, etc., and similarly, the group $(6n + 1)$ gives the harmonics 7, 13, 19, etc.

speed. There is an apparent exception to this in the case of standard generators; due to the saliency of the poles, they are capable of delivering a certain amount of power when excited from the primary. This characteristic is the result of the variation of inductance of the stator winding with varying position of the rotor, and may be regarded as a form of dissymmetry. The amount of power a machine is capable of delivering in this way is a fixed fraction of the total exciting kv-a. Steam turbine generators have very little of this characteristic.

The generator relative to the negative phase-sequence current is being driven backwards at synchronous speed, and, therefore, as we have shown, if it is a symmetrical machine, it cannot deliver any useful work at its terminals through the medium of the negative phase-sequence currents. The mechanical power at the shaft, due to the negative phase-sequence currents is completely used up in losses in the damper windings. In short, a generator cannot deliver useful power at its terminals, except through the system of e. m. fs. set up through its main field excitation. It will now be apparent that a symmetrical generator cannot deliver any other than positive phase-sequence power. All the negative phase-sequence current flowing therein represents losses; the flow of these currents requires also the application of a certain amount of mechanical torque at the driving shaft which must be supplied from the true source of power which in the case of a generator is the prime-mover.

One special form of generator should be mentioned, in which the field windings have high external reactance and the field is thoroughly laminated and is not provided with damper windings. In such a machine the impedance to negative phase-sequence current is the same as that to positive phase-sequence current. Such a machine delivering a single-phase load will have a pulsating field. Moreover, the harmonics due to the field form will not be damped out as in the machine provided with damper winding. The unbalance in voltages due to unbalanced load in such a machine will be very marked.

It is possible that a generator may give perfectly balanced voltages at no load and will be inherently unbalanced under load. The fact that a symmetrical generator cannot deliver power through the negative phase-sequence currents affords a simple check to determine whether an unbalance is wholly due to external sources or is partly inherent in the generator. The total negative sequence power output may be measured, and if it is negative, the unbalance is due mainly to external conditions; if it is positive, a great part of the unbalance is inherent.

THREE-PHASE INDUCTION MOTORS: SYNCHRONOUS MOTORS: ROTARY CONVERTERS:

The action of polyphase motors is quite similar to that of polyphase generators. Thus, if the machine is

an induction motor, at no load, the rotor, since it is rotating at near synchronous speed, is traveling at approximately the same angular velocity as the field set up by its primary currents; there is, therefore, practically no current set up in the secondary winding. The effect is similar to that in an open-circuited transformer. As a load is thrown on the motor, the speed decreases and sufficient current flows in the secondary to produce the required torque. In the case of negative phase-sequence currents in the primary, the rotor is traveling, relative to the field set up by these currents, at double synchronous speed, approximately; the effect, therefore, is similar to that in a short-circuited transformer. For a slight unbalance of the impressed voltage, a relatively larger unbalanced current will, therefore, flow. If the negative sequence input is measured, it will always be positive if the motor is tending to maintain a balance. If it should read negative, the motor is unsymmetrical, and is causing unbalance. The above analysis applies equally well in the case of synchronous motors. In the case of rotary converters, the effects of unbalance may be quite serious for the negative phase-sequence current is not commutated, but circulates in the winding and produces secondary double-frequency currents. Both primary and secondary currents may be quite large, and since the former is not compensated by the flow of direct current, it has its full heating effect in the windings. Moreover, the negative phase-sequence current in the primary sets up a double-frequency voltage between commutator segments, which increases the tendency to flash over. A certain amount of double-frequency current flows through the brushes into the d-c. system, heating the brushes and causing inductive disturbances.

In the measurement of power supplied to a symmetrical motor, we are chiefly concerned with its operation considered with reference to a balanced positive phase-sequence system which is the standard polyphase system of reference in the same way that the sine wave is the standard wave form of current and e. m. f. As pointed out in a preceding paragraph, in a symmetrical motor, the total power input which is the sum of the positive and negative sequence power, is greater than the positive phase-sequence power input and the difference constitutes loss in the motor, due to the unbalance. But this is not the only loss due to the unbalance; there is a counter torque required to assist in driving the double-frequency current through the secondary windings, and this is supplied by the positive phase-sequence power which is also increased as a result of the unbalance; the increase is, however, very small, being approximately equal to one-half the secondary loss due to the double-frequency current flowing therein, and it may practically be ignored.

It will be apparent from the above statement that the existing methods of measuring power input to motors and rotary converters are not quite equitable and penalize the machines that assist in balancing the sys-

tem while it favors those which inherently have characteristics that increase unbalance.

The simplest procedure to obtain the input of power to polyphase motors is to ignore the small additional loss due to the back torque set up by the negative phase-sequence currents in the motor, and to take the positive phase-sequence power and kv-a. or power factor as a measure of the performance of the machine. This method is a great deal more accurate than the present method of measuring the performance of the machine by the total power input and the effective power factor.

The product of negative phase-sequence current and positive phase-sequence volts, is a measure of the phase balancing or unbalancing effect of the motor on the circuit. When it is known that the motor is symmetrical, this will always measure the balancing effect of the motor on the system. When there is doubt as to the symmetry of the motor, the question as to whether its operation is favorable or detrimental to the balance of the circuit may be answered by obtaining negative sequence power input. If the value is positive, the operation is favorable; if it is negative, the operation is detrimental. There are certain cases where these criteria fail, but the number of cases in which it will be necessary to apply the test is small, and the number of cases in which the test fails is an unimportant figure.

SINGLE PHASE MOTORS

Considered from the point of view of symmetrical coordinates, single-phase motors are only a special case of three-phase motor unbalanced operation. The positive phase-sequence current and the negative phase-sequence currents are equal in magnitude; the unbalancing effect of such a motor is, therefore, quite definite and is equal to its positive phase-sequence kv-a.

It would appear reasonable to charge a consumer, using single-phase motor, on the basis of this unbalanced kv-a. whether other consumers using similar machines, when operating simultaneous with his, are connected, to jointly produce a balance or not. The cost of single-phase service on polyphase systems should be based on the cost of unbalance, compiled from the previous year.

This method of charging could be extended to all single-phase power loads, and would be equitable except in the case of consumers having mixed loads, who should be encouraged to balance up the single-phase portion of their loads as far as practicable. It should be remembered, however, that single-phase loads even when perfectly balanced are inferior to balanced polyphase rotating loads, because the latter have high inherent balancing characteristics which the single-phase balanced loads do not have. That is to say, the admittance to negative phase-sequence current for a balanced single-phase load is the same as its admittance to positive phase-sequence current, whereas in the case

of a polyphase synchronous or induction motor or rotating converter carrying the same load, admittance to negative phase-sequence current may be many times that to positive phase-sequence currents.

SINGLE-PHASE LIGHTING

The same comments apply to this type of load as to single-phase motors, except that the power factor being near unity, the lighting load becomes less objectionable from this standpoint. When it is possible to balance the loads on all phases, it should be done by the consumer as closely as practicable, and he should be charged on the basis of the polyphase power consumed and the unbalance he creates. At the present stage, it will be sufficient to charge him for his unbalanced kv-a. without considering whether he is helping or hindering the balance. This charge may be considered the penalty attached to single-phase service, which is reduced in proportion to the care with which the consumer arranges his circuits. This method of charging holds equally well for all single-phase loads where they can be arranged to give good approximate balance.

THREE-PHASE FURNACES

The three-phase furnaces may be balanced by introducing a properly designed control. With proper control, it should be balanced both as to current and e. m. f. between neutral and terminals. Under these conditions of balance such harmonics of current as occur will be a minimum. A practical method of obtaining balance, is with the use of a series phase balancer which will be small as compared with the output of the machine. This should be combined with a voltage regulator to control the depth of the electrodes; in this way perfect balance as to the current as well as voltage may be obtained. Furnace loads when balanced have no inherent balancing capacity whatever, and therefore all unbalanced kv-a. should be charged for. In addition if the wave form of current is very much distorted, some account should be taken of this distortion when the operating conditions warrant it.

EQUITABLE SYSTEM OF RATES BASED ON SEQUENCE MEASUREMENTS

The positive-phase sequence power delivered to a load may be measured by a single-element wattmeter with the proper form of network constraint which can be incorporated in the meter. It has been pointed out that this power is the only power that a generating station is capable of delivering. The total power delivered measured at the terminals of a symmetrical generator which carries an unbalanced load is always less than the positive phase-sequence power. The difference is absorbed by the generator in the form of losses. In the case of a load causing unbalance, the positive phase-sequence power input will always include the negative phase-sequence power delivered to the system by the load as a result of the unbalance. Balanced polyphase loads, such as motors and balanced

polyphase networks in general, do not contribute to the unbalance, but assist in maintaining balance. They absorb negative phase-sequence power, but do not transform positive phase-sequence power into negative phase-sequence power. Their operation as motors has nothing to do with their phase-balancing characteristics and is dependent solely on the positive phase-sequence power taken. There is a certain amount of positive phase-sequence power, so small that it may be neglected in the motor power, absorbed by reason of the balancing effect which is dissipated in the secondary windings as $I^2 R$ loss. The motor is performing an important service as a phase balancer for which, with the present method of charging, it is penalized. If only the positive phase-sequence power delivered is measured and charged for, this penalty will be removed and placed, where it should be placed, on the unbalanced loads on the system. The consumer who uses polyphase motors should get a polyphase rate somewhat lower than that for other kinds of polyphase load depending upon the estimated cost of unbalancing.

In the case of the consumer having a mixed load, if his single-phase load is of sufficient importance, it may be metered separately. If it is small as compared with the polyphase motor load, it may be connected so as to produce a minimum unbalance and the charge should be based on the positive phase-sequence meter reading and a rate obtained by taking the weighted average of the polyphase rate for single-phase balanced networks and that for polyphase motors, based on the respective value of the wired single-phase and polyphase loads.

In the case of single-phase loads connected so as to minimize unbalance, the power charges should be made on the basis of the positive phase-sequence power. A charge should also be made for negative phase-sequence kv-a. obtained by means of a recording negative phase-sequence current device, in the same manner as reactive power is charged for, the cost of unbalance being computed from previous results.

To sum up: Positive phase-sequence power is the only commodity manufactured by the power plant; phase balance is a service to which all consumers using polyphase motors contribute and with which users of single-phase devices interfere. Users of balanced polyphase power other than motors should pay for this service in the regular polyphase rates. Users of single-phase devices should pay over and above the regular polyphase rate depending upon the amount of unbalanced current they create. Users of polyphase motors should obtain a lower polyphase rate, based on the average amount of service they contribute to the maintaining of balance.

The meters required for assigning the proper charges are as simple or simpler than those used at the present time for polyphase power measurements and the results should prove more satisfactory and equitable all round and are based on correct theoretical grounds.

CHARACTERISTICS OF TRANSMISSION AND DISTRIBUTION SYSTEMS REQUIRED TO MAINTAIN BALANCED POLYPHASE SERVICE

It is essential to the maintenance of good balanced polyphase service that all banks of transformers should be symmetrically grouped that all transformers in one bank shall have the same performance and characteristics. It was not unusual in the past to find rotary converters connected to polyphase systems through a bank of open delta-connected transformers; such practises should not be tolerated except for short intervals while starting or under emergency conditions.

All feeders used to supply mixed loads should be loaded as symmetrically as possible. They should have as low impedance as possible for two reasons: (1) So that the effect of starting and stopping motors will not affect the lighting service unreasonably. (2) In order to reduce the voltage unbalance caused by any given value of unbalanced load they may incur.

Where a polyphase circuit is called upon to supply a large single-phase load, special provision should be made for the service such as heavier feeders and in many cases balancers or phase converters should be installed.

In selling power to a consumer of this kind the cost of the converter station will naturally enter into the rates charged for power, otherwise, the rates used will be the regular polyphase rates for power.

Dissymmetry in transmissions, feeders, etc. should be avoided with careful transpositions, dissymmetry in conductor arrangements may be compensated. In long transmission systems when synchronous condensers for regulating purposes are distributed over the line, they will also serve the purpose of phase balancers.

The fact that normal overloads have the characteristics of remaining balanced offers great possibilities in the way of protection on feeders selective operation and so forth. For if a loaded system is normally balanced, we may employ a positive phase-sequence relay for load control having the proper time element, and for short-circuit control, we may use the negative phase-sequence principle, and since negative phase sequence current flows only under short circuit, complete selective operation may be obtained.

There are many more applications of this principle to apparatus protection and control, too many to enumerate, that will suggest themselves to anyone who takes the trouble to study this subject.

Appendix

There appears to be a certain amount of misunderstanding in regard to the derivation of power quantities from the vector quantities used in alternating-current problems. In a recent letter, a copy of which was sent to the writer, the statement was made: "The quantity $\sum E_k I_k \sin \theta_k$ seems to me without physical significance, and as far as I am aware cannot be measured except when there are no harmonics present."

This quantity, however, has this physical significance, for example, in a constant voltage transmission system it is a measure of the magnetic energy that must be supplied to the system in order to maintain the voltage constant. It is also a measure of the capacity of the synchronous condensers required to supply the magnetic energy. In certain cases it would be impossible to supply more than a very limited amount of power, over a transmission line without supplying the necessary amount of this quantity which is stated to have no physical significance.

The fact that when harmonics are present the sum of these products cannot be measured with any known device is not of any great importance, as engineers are not greatly concerned with harmonic power quantities except in their elimination. It may be safely said that as far as the regulation of the lines and the supply thereto of magnetic energy is concerned these harmonic quantities have no practical significance.

Current and e. m. f. are from the point of view of linear circuits scalar quantities, but it is convenient to represent them by means of vector quantities. Similarly, power is a scalar quantity, and it is found equally convenient to represent it by means of a vector.

When the current and e. m. f. are simple harmonic quantities they are directly resolvable into two vectors rotating in opposite senses at uniform angular velocity. The power however, will not be a simple harmonic quantity but will consist of a mean term and a double-frequency term. The instantaneous power is therefore represented by two fixed vectors combined with two vectors rotating at double normal angular velocity in opposite directions. In both cases the two systems of vectors are conjugate and it is found convenient to ignore one system and represent those quantities by the positively rotating system. In the case of simple harmonic quantities such as current and e. m. f. a simple vector, rotating positively at an angular velocity, giving one complete revolution for each cycle is used. Power due to simple harmonic quantities is represented by a stationary vector which gives the mean power and a vector of the same magnitude rotating positively at double synchronous speed, or making one complete revolution for each half-cycle.

REPRESENTATION OF SINGLE-PHASE POWER

The representation of harmonic scalar quantities by vectors is not in any sense artificial, the relations follow at once when we express the harmonic quantities in their exponential form. The ignoring of one of the two conjugate quantities naturally follows from expediency, as it simplifies matters and makes the interpretation of formulas and equations easier.

If e and i are the instantaneous values of e. m. f. and current in a circuit and $\tilde{E}$ and $\tilde{I}$ are the corresponding symbolic expressions for these quantities the following relations hold good:

$$e = \frac{\check{E} + \hat{E}}{\sqrt{2}} \quad (1)$$

$$i = \frac{\check{I} + \hat{I}}{\sqrt{2}} \quad (2)$$

where $\hat{E}$ is conjugate to $\check{E}$ and $\hat{I}$ is conjugate to $\check{I}$, and all the symbolic terms are expressed as root mean square quantities.

e and i being simple harmonic $\check{E}$ and $\check{I}$ take the form $E e^{j\omega t}$ $I e^{j\omega t}$ when ω is 2π times the frequency.

In carrying out linear operations on i and e it is unnecessary to consider the conjugate terms $\hat{I}$ and $\hat{E}$ as the same operation on these terms yield a result which is the conjugate of that obtained by operation on $\check{I}$ and $\check{E}$. We may say therefore that i and e are fully represented by the symbolic terms $\check{I}$ and $\check{E}$, and that their actual value may be determined by either adding the conjugate term to each of these quantities and dividing by $\sqrt{2}$ or by taking the real part of these quantities multiplied by $\sqrt{2}$.

The instantaneous power delivered to the circuit is $e i$, and when the values of e and i are expressed in terms of $\check{E}$ and $\check{I}$ and their conjugates we obtain

$$e i = \frac{\check{E} \hat{I} + \hat{E} \check{I}}{2} + \frac{\check{E} \check{I} + \hat{E} \hat{I}}{2} \quad (3)$$

e and i being both simple harmonic

$$\begin{aligned} \check{E} &= E e^{j\omega t} & \hat{E} &= E e^{-j\omega t} \\ \check{I} &= I e^{j\omega t} & \hat{I} &= I e^{-j\omega t} \end{aligned}$$

so that the term $\frac{\check{E} \hat{I} + \hat{E} \check{I}}{2}$ is constant and repre-

sents the mean power. The term $\frac{\check{E} \check{I} + \hat{E} \hat{I}}{2}$ is a

harmonically varying quantity of double normal frequency and consequently its mean value is zero.

The mean power input is defined in the usual manner by the integral

$$P = \frac{1}{2\pi} \int_0^{2\pi} e i d\theta$$

where θ is equal to ωt at any instant t . If we substitute from (3) for $e i$ and carry out the integration we obtain

$$P = \frac{\check{E} \hat{I} + \hat{E} \check{I}}{2} \quad (4)$$

since the second pair of quantities in equation (3) being of double frequency becomes zero when integrated between the limits 0 and 2π .

If we have an electric system consisting of linear circuits having self-induction and mutual induction, its electromagnetic energy W is a quadratic function of the currents or $W = 1/2 L i_1^2 + M_{12} i_1 i_2 + 1/2 L i_2^2 + \dots$ Taking into account the dissipative forces we have

$$e_1 = R i_1 + \frac{d}{dt} \frac{\partial W}{\partial i_1}$$

we find that

$$1/2 R i_1 \int i_1 dt + W = 1/2 i_1 \int e_1 dt$$

$$\int e_1 dt = j \frac{\hat{E} - \check{E}}{\omega \sqrt{2}} \quad \text{for a sine wave}$$

t being measured from any convenient datum. Therefore

$$i/2 \int e_1 dt = -j \frac{\check{E} \hat{I} - \hat{E} \check{I}}{4\omega} - j \frac{\check{E} \check{I} - \hat{E} \hat{I}}{4\omega} \quad (5)$$

The mean value of this integral is therefore given by

$$-j \frac{\check{E} \hat{I} - \hat{E} \check{I}}{4\omega}$$

and this is equal to W the electromagnetic energy since the mean value of $1/2 R i_1 \int i_1 dt$ is zero. We thus have

$$W_{mean} = -j \frac{\check{E} \hat{I} - \hat{E} \check{I}}{4\omega}$$

The "reactive power" is the average flow of electromagnetic energy throughout one half-cycle from the instant that $W = 0$ to the next instant that $W = 0$ and since W is a double-frequency pulsating quantity whose average value is one half the maximum, the "reactive power" Q is given by $2\omega W$ or

$$Q = -j \frac{\check{E} \hat{I} - \hat{E} \check{I}}{2} \quad (6)$$

multiply (6) by j and add to (4) we then have

$$P + jQ = \check{E} \hat{I}$$

This product therefore defines both the true and reactive power of the circuit.

The second terms of (3) and (5) are the double-frequency portions of the power product and we find if we take

$$P_H = \frac{\check{E} \check{I} + \hat{E} \hat{I}}{2}$$

$$Q_H = -j \frac{\check{E} \check{I} - \hat{E} \hat{I}}{2}$$

$$P_H + jQ_H = \check{E} \check{I}$$

The complete symbolic expression for the power is therefore

$$(P + jQ) + (P_H + jQ_H) = \check{E} \hat{I} + \check{E} \check{I}$$

The expression $P_H + jQ_H$ however is superfluous as we are only interested in the mean values of power and furthermore, when the values of P and Q are given, the values of P_H and Q_H may be determined. It may be shown that the vector $P_H + jQ_H$ which is rotating positively at double synchronous speed will be equal in

magnitude to $P + jQ$ and coincide with it at the same instant that the vector $\vec{E}$ is in coincidence with it, and since it rotates in the positive direction with twice the angular velocity of $\vec{E}$, it will always be in advance of $\vec{E}$ by the same angle that $\vec{E}$ is in advance of the stationary vector $P + jQ$ (See Fig. 1).

In the case of wave-forms having harmonics it seems reasonable, since the heating effect of the harmonics

FIG. 1—VECTOR REPRESENTATION OF RELATION BETWEEN ZERO FREQUENCY POWER PRODUCT ($P + jQ$) AND DOUBLE FREQUENCY POWER PRODUCT ($P_H + jQ_H$) IN SINGLE-PHASE CIRCUIT

is independent, to treat each frequency independently as to both true and reactive power so that if

$$\vec{E} = \sum \vec{E}_n$$

$$\vec{I} = \sum \vec{I}_n$$

$$P + jQ = \sum \vec{E}_n \vec{I}_n = \sum (P_n + jQ_n)$$

and apparent power might then be defined by

$$\sqrt{P^2 + Q^2} = \sqrt{(\sum P_n)^2 + (\sum Q_n)^2}$$

MEASUREMENT OF POWER IN SINGLE-PHASE CIRCUITS

True power may of course be measured by a wattmeter in the usual way. To measure reactive power a wattmeter having a large inductance in series with the voltage coil may be used, connected into the circuit in the same way as the ordinary wattmeter. Assuming the resistance of the voltage coil to be negligible and taking i_0 for the current flowing in it, φ for the angle of the voltage coil relative to the current coil in which the current i is flowing (the current and voltage coils of a balance type instrument should be in non-inductive relation and therefore $M = 0$) we have

$$i_0 = 1/L \int e dt$$

The instantaneous torque is

$$F = \frac{\partial M}{\partial \varphi} i_0 i$$

$$= 1/L \frac{\partial M}{\partial \varphi} i \int e dt$$

and the mean value of the torque is

$$F_{mean} = 1/L \frac{\partial M}{\partial \varphi} \frac{1}{2\pi} \int_0^{2\pi} i d\theta \int e dt$$

$$= \frac{1}{\omega L} \frac{\partial M}{\partial \varphi} Q$$

This arrangement therefore gives the mean magnetic

energy, and when the frequency is known, the mean reactive power.

When the wave form of current and e. m. f. has harmonics this instrument gives the value of $2W_{mean}$ or the mean magnetic energy. If Q_n be the reactive power for the n th harmonic the quantity measured by the

instrument is equal to $\sum \left(\frac{Q_n}{n\omega} \right)$. There will therefore be a frequency error in the instrument.

MEASUREMENTS REQUIRED FOR COMPLETE DETERMINATION OF SINGLE-PHASE CIRCUIT

The following measurements or their equivalent are required to completely determine a single-phase circuit:

- (1) Magnitude of impressed e. m. f.
- (2) Phase of impressed e. m. f.
- (3) Magnitude of current in circuit
- (4) Phase of current in circuit.

For the last two, measurements of true and reactive power may be substituted. The second measurement is not required if the particular circuit only is under consideration. If we have measurements of e. m. f. kv-a. and power-factor, the circuit is completely determined and no other measurements are required.

MEASUREMENTS REQUIRED FOR COMPLETE DETERMINATION OF BALANCED POLYPHASE CIRCUIT

In a balanced system if e. m. f. and current are determined in one phase they will also be known in the other phases. The requirements are therefore the same as for single-phase and apply to one phase only which we shall call the "principal" phase.

REPRESENTATION OF POWER IN UNBALANCED THREE-PHASE CURRENTS

Confining ourselves to three-phase systems, we find that an unbalanced four-wire system required twelve measurements to define it completely or if expressed in symbolic form six quantities are required. If $A B C$ are the three phases these symbolic quantities may be

$$\left. \begin{array}{cc} \vec{E}_A & \vec{I}_A \\ \vec{E}_B & \vec{I}_B \\ \vec{E}_C & \vec{I}_C \end{array} \right\} \quad (7)$$

In symmetrical coordinates the six quantities will be

$$\left. \begin{array}{cc} S^0 \vec{E}_{A0} & S^0 \vec{I}_{A0} \\ S^1 \vec{E}_{A1} & S^1 \vec{I}_{A1} \\ S^2 \vec{E}_{A2} & S^2 \vec{I}_{A2} \end{array} \right\} \quad (8)$$

These are related to the quantities (7) by the simple relation

$$\left. \begin{array}{l} S^0 E_{A0} = S^0 \frac{\vec{E}_A + \vec{E}_B + \vec{E}_C}{3} \\ S^1 \vec{E}_{A1} = S^1 \frac{\vec{E}_A + \alpha \vec{E}_B + \alpha^2 \vec{E}_C}{3} \\ S^2 \vec{E}_{A2} = S^2 \frac{\vec{E}_A + \alpha^2 \vec{E}_B + \alpha \vec{E}_C}{3} \end{array} \right\} \quad (9)$$

where $\alpha = -1/2 + j\sqrt{3}/2$ $\alpha^2 = -1/2 - j\sqrt{3}/2$ exactly the same relations exist between $S^0 \tilde{I}_{A0} S^1 \tilde{I}_{A1}$ $S^2 \tilde{I}_{A2}$ and $\tilde{I}_A \tilde{I}_B \tilde{I}_C$. We have also the reciprocal relations

$$\left. \begin{aligned} \tilde{E}_A &= \tilde{E}_{A0} + \tilde{E}_{A1} + \tilde{E}_{A2} \\ \tilde{E}_B &= \tilde{E}_{A0} + \alpha^2 \tilde{E}_{A1} + \alpha \tilde{E}_{A2} \\ \tilde{E}_C &= \tilde{E}_{A0} + \alpha \tilde{E}_{A1} + \alpha^2 \tilde{E}_{A2} \end{aligned} \right\} \quad (10)$$

and corresponding relations between line currents and symmetrical coordinate currents. We sum the above up by the short hand expression

$$\begin{aligned} S^r (\tilde{E}_A) &= S^0 \tilde{E}_{A0} + S^1 \tilde{E}_{A1} + S^2 \tilde{E}_{A2} \\ S^r (\tilde{I}_A) &= S^0 \tilde{I}_{A0} + S^1 \tilde{I}_{A1} + S^2 \tilde{I}_{A2} \end{aligned}$$

The terms prefixed by $S^0 S^1$ and S^2 are respectively called the zero-phase sequence, the positive phase sequence, and the negative phase sequence components of e. m. f. or current. The sequence symbol S prefixing each of the quantities, indicates that the quantity in question is the principal one of a group of three quantities constituting a symmetrical three-phase system.

For each current or e. m. f. sequence there is a conjugate current or e. m. f. sequence which is distinguished from it by having a negative exponent

$$\left. \begin{aligned} S^0 \tilde{E}_{A0} \text{ conjugate seq } S^{-0} \hat{E}_{A0} \\ S^1 \tilde{E}_{A1} \text{ conjugate seq } S^{-1} \hat{E}_{A1} \\ S^2 \tilde{E}_{A2} \text{ conjugate seq } S^{-2} \hat{E}_{A2} \end{aligned} \right\} \quad (12)$$

The relation between instantaneous values in the symmetrical coordinate system and the vector values is exactly the same as for single-phase. Thus the system of e. m. fs. $e_a e_b e_c$ is given by

$$(e_a, e_b, e_c) = \frac{S^0 \tilde{E}_{A0} + S^{-0} \hat{E}_{A0}}{\sqrt{2}} + \frac{S^1 \tilde{E}_{A1} + S^{-1} \hat{E}_{A1}}{\sqrt{2}} + \frac{S^2 \tilde{E}_{A2} + S^{-2} \hat{E}_{A2}}{\sqrt{2}}$$

The conjugate symbol S^{-1} is as it implies, a sequence which is conjugate to S^1 . Thus, if $S^1 \tilde{E}_{A1}$ signifies the system

$$\left. \begin{aligned} \tilde{E}_{a1} &= \tilde{E}_{A1} \\ \tilde{E}_{b1} &= \alpha^2 \tilde{E}_{A1} \\ \tilde{E}_{c1} &= \alpha \tilde{E}_{A1} \end{aligned} \right\} \quad (13)$$

The conjugate system $S^{-1} \hat{E}_{A1}$ is

$$\left. \begin{aligned} \hat{E}_{a1} &= \hat{E}_{A1} \\ \hat{E}_{b1} &= \alpha \hat{E}_{A1} \\ \hat{E}_{c1} &= \alpha^2 \hat{E}_{A1} \end{aligned} \right\} \quad (14)$$

If we sum the terms of a sequence other than zero sequence the value will be always zero or

$$\Sigma (S^1 P) = 0$$

$$\Sigma (S^2 P) = 0$$

But $\Sigma (S^0 P) = 3P$ for three phase

Consider the system of e. m. fs. and currents e_a, e_b, e_c i_a, i_b, i_c . These two systems have been shown to be equal to

$$\begin{aligned} (e_a, e_b, e_c) &= \frac{S^0 \tilde{E}_{A0} + S^{-0} \hat{E}_{A0}}{\sqrt{2}} + \frac{S^1 \tilde{E}_{A1} + S^{-1} \hat{E}_{A1}}{\sqrt{2}} + \frac{S^2 \tilde{E}_{A2} + S^{-2} \hat{E}_{A2}}{\sqrt{2}} \\ (i_a, i_b, i_c) &= \frac{S^0 \tilde{I}_{A0} + S^{-0} \hat{I}_{A0}}{\sqrt{2}} + \frac{S^1 \tilde{I}_{A1} + S^{-1} \hat{I}_{A1}}{\sqrt{2}} + \frac{S^2 \tilde{I}_{A2} + S^{-2} \hat{I}_{A2}}{\sqrt{2}} \end{aligned}$$

If we take the product of these two quantities treating the sequence symbols as if they represented actual quantities we shall obtain the instantaneous power in each of the phases. The zero-frequency portion of this quantity will be considered first as it represents the mean power in each phase. It will consist of two terms which are conjugate to each other. These two terms are those obtained by taking one half the product of $S^r (\tilde{E}_a)$ and $S^{-r} (\hat{I}_a)$ or $1/2 (S^0 \tilde{E}_{A0} + S^1 \tilde{E}_{A1} + S^2 \tilde{E}_{A2}) (S^{-0} \hat{I}_{A0} + S^{-1} \hat{I}_{A1} + S^{-2} \hat{I}_{A2})$. From this, following the method of proof used for single-phase, we find that the mean power per phase may be represented by the vector sequence quantity $S^r (P_A + jQ_A)$. The mean power per phase obtained by taking the products of instantaneous values of current and e. m. f. is one half the sum of this term and its conjugate. Therefore the real part of this term represents the mean true power per phase and the imaginary part the mean flow of magnetic energy or the reactive power per phase. Using currents $i_a i_b i_c$ and e. m. fs. $e_a e_b e_c$ instead of $i_A i_B i_C$ etc.

$$\begin{aligned} S^r (P_A + jQ_A) &= (S^0 \tilde{E}_{A0} + S^1 \tilde{E}_{A1} + S^2 \tilde{E}_{A2}) (S^{-0} \hat{I}_{A0} + S^{-1} \hat{I}_{A1} + S^{-2} \hat{I}_{A2}) \\ &= S^0 (\tilde{E}_{A0} \hat{I}_{A0} + \tilde{E}_{A1} \hat{I}_{A1} + \tilde{E}_{A2} \hat{I}_{A2}) \\ &\quad + S^1 (\tilde{E}_{A0} \hat{I}_{A2} + \tilde{E}_{A1} \hat{I}_{A0} + \tilde{E}_{A2} \hat{I}_{A1}) \\ &\quad + S^2 (\tilde{E}_{A0} \hat{I}_{A1} + \tilde{E}_{A1} \hat{I}_{A2} + \tilde{E}_{A2} \hat{I}_{A0}) \end{aligned} \quad (15)$$

The symbol S^{-1} being in the three-phase system the same as S_1^2 and S^{-2} being the same as S^1 . The total mean power is $P + jQ = \Sigma S^r (P_A + jQ_A)$ or

$$(P + jQ) = 3 (\tilde{E}_{A0} \hat{I}_{A0} + \tilde{E}_{A1} \hat{I}_{A1} + \tilde{E}_{A2} \hat{I}_{A2}) \quad (16)$$

$\Sigma S^1 ()$ and $\Sigma S^2 ()$ being both equal to zero represent instantaneous power interchanges among the three phases, and are caused by unbalance. The double-frequency power product $S^r (P_{HA} + jQ_{HA})$ is given by

$$\begin{aligned} S^r (P_{HA} + jQ_{HA}) &= S^0 (\tilde{E}_{A0} \tilde{I}_{A0} + \tilde{E}_{A1} \tilde{I}_{A2} + \tilde{E}_{A2} \tilde{I}_{A1}) \\ &\quad + S^1 (\tilde{E}_{A0} \tilde{I}_{A1} + \tilde{E}_{A1} \tilde{I}_{A0} + \tilde{E}_{A2} \tilde{I}_{A2}) \\ &\quad + S^2 (\tilde{E}_{A0} \tilde{I}_{A2} + \tilde{E}_{A1} \tilde{I}_{A1} + \tilde{E}_{A2} \tilde{I}_{A0}) \end{aligned} \quad (17)$$

which is seen to be the product

$(S^0 \tilde{E}_{A0} + S^1 \tilde{E}_{A1} + S^2 \tilde{E}_{A2}) (S^0 \tilde{I}_{A0} + S^1 \tilde{I}_{A1} + S^2 \tilde{I}_{A2})$ and therefore the double-frequency product is obtained for three-phase in exactly the same way as it is obtained for single-phase, and furthermore, the amplitude and

three-phase angle of the double-frequency term for the principal phase is related to the e. m. f. of which it is composed in exactly the same way as in the case of single-phase. That is the double-frequency power vector is as much in advance of the corresponding e. m. f. vector as this vector is in advance of the corresponding mean power vector. The sequence of the double-frequency power vector is obtained from (17), that is the exponent of the sequence symbol or order of

FIG. 2—POWER VECTOR DIAGRAM

25 per cent current unbalance, 5 per cent voltage unbalance

the sequence is the sum of the exponents of the sequences of current and e. m. f.

The significance of the expression (15) is that it gives not only the mean power for each phase, but it also determines the magnitude and phase of the double-frequency power product which results from unbalance. The portions of (17) whose instantaneous sums are zero are of no significance. The important double-frequency quantities are given by

$$P_H + J Q_H = \sum S^r (P_{HA} + Q_{HA})$$

$$= 3 (\tilde{E}_{A0} \hat{I}_{A0} + \tilde{E}_{A1} \hat{I}_{A1} + \tilde{E}_{A2} \hat{I}_{A2})$$

and are seen to be double-frequency power vectors of like value and phase in each phase. These power vectors are present only when there is unbalance and they have no relation to the power factor of the system.

FIG. 3—POWER VECTOR DIAGRAM

25 per cent current unbalance. No unbalance in voltage. Illustrates the load condition at a distribution point at which a phase balancer is installed.

In a balanced system the instantaneous sum of the double-frequency power vectors is always zero.

A power vector diagram for the zero frequency power products may be drawn. This vector diagram repre-

sents the resolution of the mean power per phase into symmetrical coordinate vectors. For each of these coordinates there is a corresponding double-frequency power vector which gives the actual value of the double-frequency power at each instant.

Fig. (3) illustrates a system having about 25 per cent unbalance in current and about 5 per cent unbalance in voltage. The relative distribution of load among the three phases will depend upon the position of the triangle $A B C$ which may be rotated about its centroid without changing the total mean power but producing a marked difference in the values of mean power per phase. The unbalance factor for current is the ratio $\tilde{I}_{A2}/\tilde{I}_{A1}$ which is a complex quantity. The conjugate of this quantity gives the magnitude and position of the unbalanced power vector $S^2 \tilde{E}_{A1} \hat{I}_{A2}$ with respect to $S^0 \tilde{E}_{A1} \hat{I}_{A1}$ the quantity which gives equal values per phase and is the total mean power product or kv-a. per phase.

The vector method of representing power quantities affords a simple means of obtaining a physical picture

FIG. 4—POWER VECTOR DIAGRAM

Illustrates a single-phase load on a three-phase system, the balance of which is 100 per cent due to a phase balancer. $(O'A, O'B, O'C)$ represent the load on the balancer due to the single-phase load

of the heating effect due to unbalanced currents. In many cases the e. m. f. unbalance is small enough to be ignored in rough approximations. Take the case of a small induction motor having a negative phase sequence impedance of 15 per cent which is about an average figure; $3\frac{1}{4}$ per cent unbalance in voltage at the terminals of this motor will cause 25 per cent unbalance in current. From a practical standpoint in estimating the heating effect of the unbalance the voltage unbalance may be ignored. The mean power load will be practically the same as for balanced voltages with the addition of the kv-a. per phase due to the unbalanced current which will be added vectorially to the mean power; this will be obtained by taking the square of the unbalanced current multiplied by the negative sequence impedance. The end of this vector obtained in this manner serves as a centroid for an equilateral triangle $A' B' C'$ such that the lines drawn from the centroid to A, B , and C , are equal to 25 per cent

of the mean power per phase or the vector $S^0 \tilde{E}_{A1} \hat{I}_{A1}$. By rotating this triangle about its centroid all the different conditions of load to which the motor may be subjected on a line having this degree of unbalance are obtained. The triangle A', B', C' is drawn negative sequence. If we wish also to include the unbalance due to the voltage we may represent this by a positive phase sequence equilateral triangle whose distance from centroid to apex is $3\frac{1}{4}$ per cent of the mean power per phase. The angle this vector makes with the mean power vector is arbitrary and is the same as the angle $\tilde{E}_{A2}$ makes with E_{A1} . Let us denote it by θ_1 . Let θ_3 be the angle that the negative sequence current lags behind the negative sequence voltage, this is given by the power factor of the negative phase sequence impedance. Then the principal phase or apex A'' will be in advance of the datum line by the angle $\theta_3 - \theta$. To obtain a complete solution we should take

(1) mean power per phase $P/3 + jQ/3$ leads datum line by angle θ_2

(2) neg. seq. power per phase $\tilde{E}_{A2} \hat{I}_{A2}$ length of vector compared with $(P/3 + jQ/3)$ is given by product of current unbalance factor and voltage unbalance factor leads datum line by angle θ_3 .

(3) voltage unbalance volt. amp. $S^1 \tilde{E}_{A2} \hat{I}_{A1}$ length of vector compared with $(P/3 + jQ/3)$ same percentage as $\tilde{E}_{A2}$ is of $\tilde{E}_{A1}$ leads datum line by angle $\theta_2 + \theta_1$

(4) current unbalance volt amperes $S^2 \tilde{E}_{A1} \hat{I}_{A2}$ length of vector compared with $P/3 + jQ/3$ or $\tilde{E}_{A1} \hat{I}_{A1}$ is same percentage as $\hat{I}_{A2}$ is of $\hat{I}_{A1}$ or unbalance factor leads datum line by angle $\theta_3 - \theta_1$.

Each of the systems of vectors $S^2 \tilde{E}_{A1} \hat{I}_{A2}$, $S^1 \tilde{E}_{A2} \hat{I}_{A1}$ will give an equilateral triangle whose centroid is the end of the vector $S^0 (\tilde{E}_{A1} \hat{I}_{A1} + \tilde{E}_{A2} \hat{I}_{A2})$. The two combine to form a triangle not equilateral which may be rotated about its centroid at the end of the mean power vector to give the power per phase for all possible conditions of load, thus the complete range of possible values of kv-a. per phase may be obtained by the lengths of the vectors OA, OB, OC drawn from the origin to the apices of the composite triangle.

A study of the diagram will show that the quantities measuring unbalance do not affect the true mean power and power factor, and therefore any attempt to deduce a factor which will simultaneously take account of both power factor and unbalance is useless. The positive and negative sequence current, voltage, true power, reactive power, etc. may all be measured with single element meters and a suitable constraining network. Mr. Evans has kindly undertaken to describe in the discussion some of those which have been developed.

Applying the principles outlined above it is easy to prove that a symmetrical generator can deliver power only through the positive phase sequence current it delivers to the system, and that any power due to negative phase sequence current is absorbed as losses in the

generator. This is also true of all symmetrical rotating machines on the system, any power due to negative phase sequence current is absorbed in the form of additional losses.

In the body of the paper the task has been undertaken of showing that unbalance is of the same order of importance as power factor. If we denote by $\tilde{E}_1$ the terminal e. m. f. of one winding of a generator and by $\tilde{E}_0$ the e. m. f. that would appear at the terminals if

$$P + SQ = (\tilde{E}_{A1} \hat{I}_{A1} - \hat{I}_{A1} Z_1) \hat{I}_{A1} - \hat{I}_{A1}^2 Z_2$$

$$OA', OB', OC' = -S^2 (\tilde{E}_{A1} \hat{I}_{A1} - \hat{I}_{A1} Z_1) \hat{I}_{A1}$$

$$(OA'', OB'', OC'') = S^1 \hat{I}_{A1}^2 Z_2$$

$$\hat{I}_{A1} = -\hat{I}_{A2}$$

FIG. 5—POWER VECTOR DIAGRAM

Single-phase generator supplying power (OA, OB, OC) represent loads on phase A, B and C respectively

the current were zero, and if $r_1 I$ be the resistance drop $j \times \hat{I}_1$ the e. m. f. due to the component of the field set up by the stator m. m. f. including the internal leakage field

$$\tilde{E}_0 = \tilde{E}_1 + (r_1 + j x_1) I_1$$

The phase and magnitude of $\tilde{E}_0$ will depend upon the time phase of I_1 . Since $\tilde{E}_0$ is the component due to the exciting current I_0 we may use the coefficient of mutual induction M_0 to give the generated voltage in terms of the exciting current

$$\tilde{E}_0 = j \omega M_0 I_0 e^{j\omega t}$$

and therefore

$$j \omega M_0 I_0 e^{j\omega t} = \tilde{E}_1 + (r_1 + j x_1) I_1$$

In particular if we take E_1 as datum and if $\hat{I}$ is lagging in time phase behind E_1 by a quarter cycle

$$j \omega M_0 I_0 e^{j\omega t} = E_1 e^{j\omega t} + (r_1 + j x_1) (-j I_1) e^{j\omega t}$$

$$j \omega M_0 I_0 = (E + x_1 I) - (j r I)$$

Thus if we ignore the value of $r_1 I_1$ which is small, the increase in the exciting current required to maintain a given terminal e. m. f. under zero power factor load is proportional to I

$$\Delta I_0 = \frac{x_1}{j \omega M_0}$$

showing that the presence of wattless lagging current in the winding necessitated a proportional increase in the exciting current. The cyclic changes in saturation will not affect the value of M_0 which is the average

value. But the average value will change with the strength of the resultant field, but on account of the long air gaps, these changes are not so important as might be supposed.

When the terminal voltages are unbalanced they may be resolved into their positive and negative phase sequence components $S^1 \tilde{E}$ and $S^2 \tilde{E}_2$ so that we have

$$S \tilde{E} = S^1 \tilde{E}_1 + S^2 \tilde{E}_2$$

we have further

$$S^1 \tilde{E}_1 = S^1 (j \omega M_0 I_0 e^{j\omega t} - Z_1 \tilde{I}_1)$$

$$S^2 \tilde{E}_2 = S^2 (0 - Z_2 \tilde{I}_2)$$

the generated negative sequence voltage in a symmetrical generator being zero. This gives

$$S^1 \tilde{E}_0 = S^2 (\tilde{E}_1 + Z_1 \tilde{I}_1)$$

$$S^2 0 = S^2 (\tilde{E}_2 + Z_2 \tilde{I}_2)$$

The total current is

$$S^r (\tilde{I}) = S^1 \tilde{I}_1 + S^2 \tilde{I}_2$$

$$\text{conjugate } S^{-r} (\tilde{I}) = S^{-1} \tilde{I}_1 + S^{-2} \tilde{I}_2$$

The power generated

$$P_0 + j Q_0 = \Sigma [S^1 \tilde{E}_0 + S^2 (0)] [S^{-1} \tilde{I}_1 + S^{-2} \tilde{I}_2] = 3 (\tilde{E}_0 \tilde{I}_1)$$

which shows that no power is generated through negative sequence current, but such as appears at the generator terminals is power that was originally generated by the machine through positive sequence voltage and current which has been degraded through some unbalanced load and fed back into the system in the form of negative phase sequence voltage and current, producing increased losses and heating.

The total heating due to $\tilde{I}_2$ in the stator windings will be obtained correctly by considering $\tilde{I}_2$ as entirely independent of $\tilde{I}_1$. The losses due to the double-frequency current in the rotor which arises from $\tilde{I}_2$ will also cause independent heating so that the total copper loss in the machine is obtained by the power product $3 (I_1^2 Z_1 + I_2^2 Z_2)$, the real part being the true copper loss. This may be obtained by considering the output of the machine at its terminals; this is given by

$$P + j Q = \Sigma (S^r \tilde{E}_A \times S^{-r} \tilde{I}_A)$$

$\tilde{E}_A$ being the terminal voltage and $\tilde{I}_A$ the conjugate of the terminal current with particular reference to phase A as principal phase

$$S^{-r} \tilde{I}_A = S^1 \tilde{I}_1 + S^2 \tilde{I}_2$$

$$\tilde{I}_A = \tilde{I}_1 + \tilde{I}_2$$

$$\tilde{I}_B = \alpha^2 \tilde{I}_1 + \alpha \tilde{I}_2$$

$$\tilde{I}_C = \alpha \tilde{I}_1 + \alpha^2 \tilde{I}_2$$

and the terminal e. m. f.

$$S^r \tilde{E}_A = S^1 (\tilde{E}_0 - \tilde{I}_1 Z_1) - S^2 \tilde{I}_2 Z_2$$

$$\tilde{E}_A = \tilde{E}_0 - Z_1 \tilde{I}_1 - Z_2 \tilde{I}_2$$

$$\tilde{E}_B = \alpha^2 \tilde{E}_0 - Z_1 \alpha^2 \tilde{I}_1 - Z_2 \alpha \tilde{I}_2$$

$$\tilde{E}_C = \alpha \tilde{E}_0 - Z_1 \alpha \tilde{I}_1 - Z_2 \alpha^2 \tilde{I}_2$$

$$\text{where } \alpha = -1/2 + j \sqrt{3}/2 \quad \alpha^2 = -1/2 - j \sqrt{3}/2 \quad \alpha^3 = 1$$

$$\begin{aligned} \Sigma (S^r \tilde{E}_A \cdot S^{-r} \tilde{I}_A) &= \Sigma [S^1 (\tilde{E}_0 - Z_1 \tilde{I}_1) \\ &\quad - S^2 Z_2 \tilde{I}_2] (S^{-1} \tilde{I}_1 + S^{-2} \tilde{I}_2) \\ &= \Sigma [S^0 (\tilde{E}_0 \tilde{I}_1 - Z_1 \tilde{I}_1^2) - S^0 I_2^2 Z_2 \\ &\quad + S^2 (\tilde{E}_0 - \tilde{I}_1 Z_1) \tilde{I}_2 - S^1 \tilde{I}_2 \tilde{I}_1 Z_1] \\ &= 3 (\tilde{E}_0 \tilde{I}_1 - I_1^2 Z_1 - I_2^2 Z_2) \end{aligned}$$

$3 \tilde{E}_0 \tilde{I}_1$ is the output of the generator not including the copper losses. The real part of $(I_1^2 Z_1 + I_2^2 Z_2)$ therefore gives the total copper loss.

The solution of the system may of course be obtained by the methods used in ordinary linear circuits having

FIG. 6—VECTOR DIAGRAM OF E. M. Fs.

Single-phase generator supplying power. Obtained from Fig. 5

mutual inductances. If we have a three-phase machine with winding impedances $Z_{11} Z_{22} Z_{33}$ and mutual impedances $Z_{12} Z_{23} Z_{31}$ etc. we have the following relations in a symmetrical machine

$$Z_{11} = Z_{22} = Z_{33} = Z_1 + Z_2$$

$$Z_{12} = Z_{23} = Z_{31} = \alpha^2 Z_1 + \alpha Z_2$$

$$Z_{13} = Z_{21} = Z_{32} = \alpha Z_1 + \alpha^2 Z_2$$

Conversely we have for Z_1 and Z_2 in terms of the impedances $Z_{11} Z_{12}$ etc.

$$Z_1 = \frac{Z_{11} + \alpha Z_{12} + \alpha^2 Z_{13}}{3}$$

$$Z_2 = \frac{Z_{11} + \alpha^2 Z_{12} + \alpha Z_{13}}{3}$$

The equations of the generator in terms of the impedances $Z_{11} Z_{12}$ etc. are

$$\left. \begin{aligned} \tilde{E}_A &= \tilde{E}_0 - Z_{11}/3 \tilde{I}_A - Z_{21}/3 \tilde{I}_B - Z_{31}/3 \tilde{I}_C \\ \tilde{E}_B &= \tilde{E}_0 - Z_{12}/3 \tilde{I}_A - Z_{22}/3 \tilde{I}_B - Z_{32}/3 \tilde{I}_C \\ \tilde{E}_C &= \tilde{E}_0 - Z_{13}/3 \tilde{I}_A - Z_{23}/3 \tilde{I}_B - Z_{33}/3 \tilde{I}_C \end{aligned} \right\} \quad (18)$$

The relations

$$\left. \begin{aligned} \tilde{I}_A + \tilde{I}_B + \tilde{I}_C &= 0 \\ Z_{11} + Z_{12} + Z_{13} &= 0 \\ \tilde{E}_A + \tilde{E}_B + \tilde{E}_C &= 0 \end{aligned} \right\} \quad (19)$$

reduce the number of independent variables in these equations to two but there is not much simplification introduced.

The above solution illustrates the difference between the method of solution which consists in considering each phase as an independent single-phase circuit and that in which the effects of the currents in all phases in symmetrical groups are considered simultaneously. Equations (18) and (19) are the forms to which the differential equations reduce on solution for steady conditions. The impedances Z_{11} Z_{12} Z_{13} etc. are compounded of two impedances Z_1 and Z_2 which are fundamental characteristic impedances of the machine and it is interesting to note that the form of these impedances bears the same relation to Z_1 and Z_2 that the currents $\tilde{I}_A$ $\tilde{I}_B$ $\tilde{I}_C$ bear to $\tilde{I}_1$ and $\tilde{I}_2$.

THREE-PHASE POWER MEASUREMENTS

It is convenient to represent line currents, and, e. m. fs. measured from the neutral point, by $\tilde{I}_A$ $\tilde{I}_B$ $\tilde{I}_C$, $\tilde{E}_A$ $\tilde{E}_B$ $\tilde{E}_C$ respectively and the corresponding sequence quantities by $S^0 \tilde{I}_{A0}$ $S^1 \tilde{I}_{A1}$ $S^2 \tilde{I}_{A2}$ etc. Delta currents and e. m. fs. between lines are represented by $\tilde{I}_a$ $\tilde{I}_b$ $\tilde{I}_c$, $\tilde{E}_a$ $\tilde{E}_b$ $\tilde{E}_c$ as shown in Fig. (7) the positive direction being indicated by an arrowhead. This gives the

FIG. 7—DIAGRAM ILLUSTRATING CONVENTION USED IN STAR AND DELTA CURRENTS BY SYMMETRICAL COORDINATES following relations between the line currents, delta currents, Y voltages and delta voltages

$$S^r \tilde{E}_A = S^1 \tilde{E}_{A1} + S^2 \tilde{E}_{A2}$$

$$S^r \tilde{E}_a = S^1 j \sqrt{3} \tilde{E}_{A1} - S^2 j \sqrt{3} \tilde{E}_{A2}$$

So that $S^1 \tilde{E}_{a1} = S^1 j \sqrt{3} \tilde{E}_{A1}$

$$S^2 \tilde{E}_{a2} = S^2 - j \sqrt{3} \tilde{E}_{A2}$$

With these relations the various methods of measuring power in three-phase circuits may be easily proved.

Three-Phase Power with Two Wattmeter

$$\begin{aligned} P + jQ &= \Sigma (S^1 \tilde{E}_{A1} + S^2 \tilde{E}_{A2}) (S^{-1} \tilde{I}_{A1} + S^{-2} \tilde{I}_{A2}) \\ &= \Sigma [S^0 (\tilde{E}_{A1} \tilde{I}_{A1} + \tilde{E}_{A2} \tilde{I}_{A2}) + S^2 \tilde{E}_{A1} \tilde{I}_{A2} \\ &\quad + S^1 \tilde{E}_{A2} \tilde{I}_{A1}] \end{aligned}$$

The sum of the instantaneous values of all but the S^0 group is zero. We may therefore add to the e. m. f. any quantity which will give S^1 and S^2 groups with no S^0 group without changing the value of the S^0 term. Thus if we add to $S^r \tilde{E}_A$ any S^0 term we shall not change the mean power. If we add $-S^0 (\tilde{E}_{A1} + \tilde{E}_{A2})$; this will make the power in phase A zero. The wattmeter in this

phase may therefore be dispensed with. This will add $-S^2 (\tilde{E}_{A1} \tilde{I}_{A2} + \tilde{E}_{A2} \tilde{I}_{A1})$ and $-S^1 (\tilde{E}_{A1} \tilde{I}_{A2} + \tilde{E}_{A2} \tilde{I}_{A1})$ to the power product. The voltages will be

$$\tilde{E}_A = \tilde{E}_{A1} + \tilde{E}_{A2} - \tilde{E}_{A1} - \tilde{E}_{A2} = 0$$

$$\tilde{E}_B = \alpha^1 \tilde{E}_{A1} - \tilde{E}_{A1} + \alpha \tilde{E}_{A2} - \tilde{E}_{A2} = \tilde{E}_C$$

$$\tilde{E}_C = \alpha \tilde{E}_{A1} - \tilde{E}_A + \alpha^2 \tilde{E}_{A2} - \tilde{E}_{A2} = -\tilde{E}_B$$

We have therefore the line currents $\tilde{I}_B$ $\tilde{I}_C$ in the series coils and the voltages $\tilde{E}_B$ and $-\tilde{E}_C$ across the shunt coils. It should be noticed that the addition of S^0 in any quantity to the e. m. f. will not affect the mean power, and therefore we may impress the voltage to the lines from any convenient point without changing the mean power. Graphically this is shown by the fact that the S^0 power product determines the mean power and the centroid of the triangles defining the amount of unbalance. Displacing the neutral point merely adds S^1 and S^2 products to the power and these represent equilateral triangles having their centroids coinciding with the end of the mean power factor.

SINGLE-PHASE GENERATOR

In the single-phase generator we have a generated symmetrical e. m. f. $\tilde{E}_0$ and at the terminals e. m. fs. $S^1 \tilde{E}_{A1}$ and $S^2 \tilde{E}_{A2}$. Furthermore if $S^1 \tilde{I}_{A1}$ be the positive phase sequence current $-S^2 \tilde{I}_{A1}$ will be the negative phase sequence current and therefore

$$S^1 (\tilde{E}_0 - Z_1 \tilde{I}_{A1}) = S^1 \tilde{E}_{A1}$$

$$S^2 \tilde{E}_{A2} = S^2 Z_2 \tilde{I}_{A1}$$

Then $S^1 \tilde{E}_{A1} + S^2 \tilde{E}_{A2} = S^1 (\tilde{E}_0 - Z_1 \tilde{I}_{A1}) + S^2 Z_2 \tilde{I}_{A1}$

$$S (P_A + jQ_A) = S^0 (\tilde{E}_0 - Z_1 \tilde{I}_{A1}) \tilde{I}_{A1}$$

$$- S^0 (Z_2 \tilde{I}_{A1}^2) - S^2 (\tilde{E}_0$$

$$- Z_1 \tilde{I}_{A1}) \tilde{I}_{A1} + S^1 (Z_2 \tilde{I}_{A1}^2)$$

The mean output per phase $P + jQ$ is therefore $S^0 (\tilde{E}_0 - Z_1 \tilde{I}_{A1}) \tilde{I}_{A1} - S^0 (Z_2 \tilde{I}_{A1}^2)$ so that the addition of the vectors $-S^2 (\tilde{E}_0 - Z_1 \tilde{I}_{A1}) \tilde{I}_{A1} + S^1 (Z_2 \tilde{I}_{A1}^2)$ makes the power in the A phase zero as it should be.

The vector diagram may be drawn as follows: Draw from the origin O the line OO' equal to $P + jQ$. The value of $\tilde{I}_{A1}$ is known it is $P + jQ$ divided by the Y voltage corresponding to the value of the single-phase terminal voltage. Through the point o' draw the vectors $S^1 \tilde{I}_{A1}^2 Z_2$ giving $O'A'' O'B'' O'C''$ in positive phase sequence relation. Draw $O'A'$ parallel and equal to $A''O$, $O'A'$ will then be the principal vector of the system $-S^2 (\tilde{E}_0 - Z_1 \tilde{I}_{A1}) \tilde{I}_{A1}$. Complete the system by the lines $O'B' O'C'$ in negative sequence relation with $o'A'$. The resultant of the systems $S^1 \tilde{I}_{A1}^2 Z_2$ and $-S^2 (\tilde{E}_0 - Z_1 \tilde{I}_{A1}) \tilde{I}_{A1}$ represented respectively by the equilateral triangles $A''B''C''$ and $A'B'C'$ combined give the triangle ABC of which the apex A lies on the point O and the lines OB and OC represent the power delivered by the phases B and C and these vectors are also proportional to the voltage to neutral of these two phases under load. The datum of $P + jQ$ represents also the phase of $\tilde{I}_B$ and $\tilde{I}_C$ in drawing the diagram. Fig. 6.

Discussion

R. D. Evans: The proper method of making measurements on polyphase circuits has been the subject of considerable discussion within the last few years. With balanced circuits, the methods were rather generally accepted, but this was not the case with unbalanced circuits. It is recognized that if the definitions and methods of measurement for polyphase circuits were to have any assured standing, they should cover the unbalanced circuit. Unbalanced polyphase circuits were not well understood, and consequently there has been a lag in the development of corresponding measuring systems.

A method for analyzing unbalanced polyphase circuits was presented before the Institute by C. L. Fortescue in his paper on "Symmetrical Coordinates". Subsequently, it is found that the various quantities used in the analysis of the unbalanced circuit could be measured. In the present paper, Mr. Fortescue has applied this method to the question of the measurement of power for the general case of the polyphase circuit, viz., the unbalanced circuit. Three conclusions of this study may be stated as follows: 1. The present basis for the energy charge is not fundamentally correct, and a new basis is proposed. 2. Power factor should be defined as being distinct from unbalance. 3. The use of an unbalance factor is desirable in metering polyphase circuits when there is appreciable unbalance.

That the present basis for the energy charge for electrical power is open to criticism may be surprising, the explanation however, lies in the fact that the special, rather than the general case of a polyphase circuit has hitherto been given consideration. Mr. Fortescue has pointed out that a customer with rotating machinery on the same line with a customer drawing a large single-phase load such as an electric furnace load, will have an energy charge in excess of that which would occur if the loads were balanced. Instead of employing the present basis for the energy charge, it would appear more equitable to charge the furnace customer with the energy which he consumes and also with the energy which he causes to be dissipated in the rotating machinery, and at the same time, not to charge the rotating machinery customer with the energy dissipated in the damper windings of his machines, due to unbalance. Mr. Fortescue proposes to do this very thing by basing the energy charge on what he terms "positive sequence power". This charge is in reality based on a component of the total power in the system, which quantity may be measured by a wattmeter of the ordinary type with suitable supplementary net work. As has been pointed out, this method would not appreciably modify the aggregate energy charge, but would distribute it more equitably. The success of the system proposed, will depend in a large measure on the reliability, simplicity and cost of the necessary metering equipment. Some of these metering devices will be described and their operation will be explained in a general way.

The method proposed by Mr. Fortescue for analyzing unbalanced circuits is based on the fact that any unbalanced system may be resolved into two or more balanced or symmetrical systems. For example, in a three-phase three-wire circuit an unbalanced system of current may be resolved into two symmetrical three-phase systems, in which the currents of one system reach their maxima in the different phases in a positive sequence as A, B, C, and the currents of the other system reach their maxima in the negative sequence C, B, A. The method used here of resolving currents into components, positive and negative sequence, is similar to the method now in general use for resolving currents into components in phase or active, and out of phase or reactive. The reason for the resolution of the currents into components for the two cases are the same, viz., that the different components have different effects, thus simplifying the solution of the problem. Each of these phase sequence quantities if present on a polyphase circuit may be measured. The method of separating out these components is accomplished

by the use of suitable supplementary net works. In general, the method for measuring these phase sequence quantities is based upon a separation of positive and negative sequence components of voltages and currents, which are used separately for the measurement of sequence voltages or currents, or which are used in combination for the measure of sequence watts, reactive watts, power factor or unbalance. The method may be described for a positive sequence device as involving a meter element in connection with a net work such that positive sequence voltage or current will cause current flow through the meter element and negative sequence voltages or currents will not. Similarly, the negative sequence device consists of a meter element in connection with a net work such that negative

FIG. 1

sequence voltage or current will cause current to flow through the meter element and positive sequence voltages or currents will not. A detailed explanation of the operation of some of the simpler forms of phase sequence devices was given before the Institute by the speaker in a paper relating to the definition of power factor on unbalanced circuits. The *Electrical World* has recently published an explanation of the operation of the sequence devices.

The speaker is however, interested principally in pointing out the type of measuring devices required for these phase sequence quantities. For simplicity, only devices for the three-phase, three-wire system will be shown. In Figure 1, the sequence voltmeter devices are shown diagrammatically. The meter on the left measures positive sequence voltage and

FIG. 2

consists of a meter element, a resistor and a reactor which constitute the supplementary net-work, and the potential transformers. The negative sequence voltmeter is shown on the right and the same apparatus is involved only a difference in connection is required. In Figure 2, the sequence current devices are shown diagrammatically. The positive sequence ammeter is shown on the left with ammeter element, resistor and reactor, which constitute the supplementary net work and the current transformers. If both positive and negative sequence voltages of a circuit are desired, they may be obtained from one set of potential transformers as shown in Figure 3. The corresponding devices for measuring positive and negative sequence current are shown in Figure 4. The schemes shown in Figs. 1 to 4 inclusive indicate how positive and negative se-

quence voltages may be separated and measured independently. These net work arrangements may be used to separate the sequence voltages and currents which may be combined to measure for example, positive sequence watts. In Figure 5 is shown positive and negative sequence wattmeters. The positive sequence wattmeter is shown on the left with negative sequence wattmeter on the right. R and Z represent resistors and reactors which constitute the supplementary net work.

With reference to the sequence devices in general, the speaker

Positive and Negative
Sequence Voltmeters

FIG. 3

Positive and Negative
Sequence Ammeters

FIG. 4

Positive and Negative Sequence Wattmeters

FIG. 5

wishes to emphasize that standard types of meter elements or relays and standard types of instrument transformers may be employed. The supplementary net work consists only of resistors and reactors. By these means, reliability and accuracy are insured. It is to be pointed out that the form of net work restraint here employed is of a type permitting higher accuracy, as reactors without resistance or resistors without reactance are not required.

With the proposed sequence system, there will result either more complete indication of circuit conditions or fewer metering

elements. With the sequence measuring system, there are particular advantages resulting from the use of the quantities thus made available. For example, Mr. Fortescue has proposed that the energy charge be measured by the positive sequence wattmeter. Another example is the application of the negative sequence current device as a relay to provide protection against single-phase operation of motors.

In conclusion, the speaker wishes to emphasize the simplicity of the sequence measuring system. In considering the application of the proposed system of measuring devices, there are two cases to be considered. First, with no unbalance present, in which case, the proposed system and the present systems give the same result, and the proposed system has the advantage of employing fewer metering elements than used with the present system. Second, with unbalance present, in which case, the two systems will give different results, and it is probably desirable to give special consideration to unbalance, which is best measured by the system proposed.

V. Karapetoff: I fully realize the importance of the principle of resolution of an unbalanced polyphase system of currents or voltages into two balanced or symmetrical systems of opposite rotation; and this method has been and will be in the future of inestimable value in numerous problems. However, when it comes to a proposal to use this system for charging customers for energy consumed or even for the maximum demand principle, I believe there will be difficulties which are well-nigh insurmountable. The very necessity of convincing

FIG. 6

regulating bodies, public service commissions, of the soundness of this principle would be a big job. Besides, the average consumer will have to understand what is meant by two systems of opposite rotation, and that the energy of each system has to be charged for, and how much he ought to be charged.

This matter has been presented and discussed at length at one of the preceding Annual Meetings, and as a result of that discussion, I tried to evolve a different principle of metering, perhaps not so sound theoretically, but one that may be much more easily understood by an average consumer of energy, and by an average member of a public service commission. I shall illustrate this principle by means of a hydraulic analogue.

The three horizontal lines A, B, C, in Fig. 6 represent pipes through which water is being delivered to a common reservoir D at the following rates: 24 gallons per minute in A; 16 gallons per minute in B, and 2 gallons per minute over the pipe C. The pumps are denoted a, b, c, and the common intake is E.

Here is an analogue of an unbalanced polyphase system. The consumer needs $24 + 16 + 2 = 42$ gallons per minute; but instead of opening the three valves uniformly, the operator opens one valve wide, another less wide, and the third one just a little until he gets a total of 42 gallons per minute. It is an easy problem to explain to the manager that it makes a considerable difference from the point of view of the pump and pipe equipment whether $42/3 = 14$ gallons per minute is delivered through all the three pipes, or 24, 16 and 2 respectively. We

surely will not say, "What difference does it make to you as long as you deliver 42 gallons per minute." We, as engineers, feel that the consumer of that careless type ought to be penalized.

Now, the question is how much should a consumer be penalized who opens one valve wide, and another a little, as compared to what he would pay had he opened the three valves to the same extent? This, and not two opposite vector rotations, is a right kind of approach to the men to whom we sell electricity, and to those who govern the rates at which it is sold. In the figure, 24 can be replaced by 14 plus 10; 16 can be replaced by 14 plus 2; and 2 can be replaced by 14 minus 12. That is, in each pipe we resolve the actual discharge in each pipe into the uniform flow 14, plus or minus the excess or deficiency as compared to that flow. We can explain to the consumer that what he does is this: He takes 14 gallons per minute through each pipe; that makes 42. In addition to this, he creates a *circulation of water*. This circulating water flows at the rate of 10 gallons through *A*, 2 gallons through *B*, with a common return through *C*. If the pumps *a*, *b*, *c*, are good only for 14 gallons per min., then additional pumps have to be installed because of the unbalance. Of course, these pumps will merely churn water, without lifting it to his reservoir, but any practical man will agree that if in addition to taking water at a uniform rate, he forces the producer to install pumps to circulate water, he has to pay for it. He can also see that the rate for this additional unbalanced water should be different from the rate which water is delivered to his reservoir for consumption.

From this mechanical analogue, a system of metering has been developed, which permits of separating the average flow of electric energy actually consumed from the energy that is merely circulated due to unbalanced load. By using another set of meters, with their potential windings in quadrature, the reactive energy unbalance can be determined. With such meters installed, you can read the energy consumed, the energy circulated, the reactive energy that is uniform, in the three phases and the amount of reactive energy circulated. It remains only to multiply each by the agreed unit rate and to add the results.

E. P. Peck: The two papers, one on Measurement of Power Balance in Polyphase Circuits and the other one, Kilovolt-ampere Demand Measurement, are very distinct technically, but in their application they merge, because they both work back into the question of measuring something that you are going to sell and the determination and application of a rate for what you sell.

The rate, to be workable, must be understandable, and it should be simple. As brought out in one of the papers, there were 418 rates investigated; 59 of them had power factor clauses, and a relatively few of those 59 power clauses were actually enforced in the collection of the bills.

We made an investigation somewhat similar to this in which we found that a good many companies were not putting in power factor rates, and very few of the companies that have power factor rates were enforcing them. Apparently this is for the reason that a business man or a manufacturer could not be made to understand what power factor was. Horse power means something to him, but even the terms "kilowatt" and "kilowatt hour" give him considerable trouble.

One of the men in the Company came down to my office a few months ago, and he said: "I have been with the Company for years and years and I have heard of power factor for years and years. Now, can you tell me in about five minutes what power factor is?" I talked about fifteen minutes, and he said he understood what power factor was in a rather general way.

You cannot, in general, use a factor in your rate which cannot be understood by a man who is paying money for his service; he must understand what he is paying money for.

For that reason, the more recent proposal of changing to a

kv-a. rate, particularly for demand, is appealing. You can explain, so that a man can understand what you are talking about, what the kv-a. is, and if he can understand and see the justice of paying on a kv-a. basis, you do not have the objection that you would have otherwise.

Now, in the proposal of including another element—the unbalance in the rate, I think, as Dr. Karapetoff just brought out, you are bringing in something that is still less understandable, and therefore still less applicable. I do not believe it could be applied at all. That would set up a rate with an energy charge, an unbalance charge, and the power factor, or a kv-a. charge.

It appears at first glance, or as far as I have been able to see, unnecessary to apply an unbalance charge, for the reason that at certain periods you can check up on your circuits, readjust the taps on the circuit, so as to get an approximate balance. That has been the standard practise in different companies with which I have been connected for a number of years. The result is that the circuits are always commercially balanced.

It appears inadvisable to bring the unbalance factor into the rate for another reason, that is, it is not, as far as I have been able to see, one of the dominant factors in your cost of supplying service, and, of course, your rate is quite largely based on the element of cost of supplying that particular customer.

The distance from the generating station to the customer has a good deal to do with your investment in transmission and distribution; the voltage that you serve your customer at has a large influence on the investment; and, of course, as your investment changes, your carrying charges, and consequently the cost to the company, changes.

A difference in load factor on your plant, whether steam or hydro, has a tremendous effect on your rate; on Sunday night your load is very light, and your cost per kilowatt hour is away up. On Tuesday, at 2 o'clock, when your load is very heavy, your investment is working pretty hard, your steam plant is working efficiently, your cost per kilowatt hour is only a fraction of what it was on Sunday night, and you cannot differentiate between those two conditions.

There are a number of other things that change your costs, not in a ratio of three-quarters of one per cent to one per cent, but change it several hundred per cent.

Since so many of those things have to be absolutely neglected, it would not seem advisable to include a factor in the rate which represented a relatively minor element of the cost. Of course it is advisable to make an analysis of all of these things, so that you have a knowledge of the different factors involved.

I must confess I had not thought of this particular element in cost before, but I do not think that it would work out well in a practical rate schedule.

R. C. Fryer: After listening to Dr. Karapetoff's remarks I would like to introduce some ideas from another viewpoint. The metering methods presented by Mr. Fortescue appear to be complicated, however, it is only through close and careful analysis of the most complicated conditions that the simplified conditions can be obtained. It is perhaps best not to discourage the development outlined in such papers as read by Mr. Fortescue but to encourage this development since the actual use of such methods will never take place until the economy of the situation so dictates.

It is quite certain that these fundamentals which are being worked out are not going to be put into use until they are tried and approved. Would it not then be better to encourage such studies knowing that they will lead to a similar analysis which may be the simplified condition so desired?

W. V. Lyon: It seems to me that Mr. Fortescue has outlined the effects of power factor and unbalanced factor both from the standpoint of the producer and the consumer of electric energy exceptionally well. There is no doubt that in time, both of these factors will be considered when metering electric energy. In commercial circuits, the effects of harmonics in the electromotive

force and current may be disregarded ordinarily and then the readings of recording, active and reactive wattmeters and positive and negative sequence ammeters and wattmeters, may be used in determining equitable charges.

I am also wholly in accord with Mr Fortescue's statement in the first sentence of the appendix. It seems to me that there is need to go no farther than the next two paragraphs for evidence of this belief. It should be said that the quoted sentence had reference, not to the metering of energy in commercial circuits, but to a proper definition of power factor. The aspects of the question may be entirely different when considered from a commercial rather than from a scientific point of view. Definitions and modes of measurements that are good practise may be entirely unsuited to form the basis of scientific definitions.¹ Thus it is with the quantity $\sum E_k I_k \sin \theta_k$. In commercial circuits where the electromotive force and current are sufficiently near the sinusoidal in wave form this quantity is approximately equal to $E_1 I_1 \sin \theta_1$. In this case it is all that Mr. Fortescue claims except that the description of the derivation of its value as shown in equation (6) is somewhat ambiguous. $E_x I \sin \theta$, omitting the subscripts (1), is ordinarily called the reactive power. It is the maximum rate at which energy flows into the magnetic field. It is also equal to the average value of the stored magnetic energy multiplied by 2ω , where $\omega = 2\pi$ times the frequency of the electromotive force and current. If the resistance and inductance of the circuit do not vary throughout the cycle, the second of these definitions is still correct even though the electromotive force and current are non-sinusoidal. The first definition, however, fails except when the electromotive force and current are both sinusoidal. If the inductance varies throughout the cycle as does that of a synchronous motor, in which the maximum variation on either side of the average may be as much as 30 per cent, neither of these definitions is in accord with physical facts. As Mr. Fortescue points out, a reactive wattmeter can be calibrated to read the average value of the stored magnetic energy even though the current and voltage may not be sinusoidal, provided, however, the resistance and inductance of the circuit do not vary cyclically. The quantity $\sum E_k I_k \sin \theta_k$, however, is not even proportional to the average value of the stored magnetic energy, nor to the reading of a reactive wattmeter, except when the subscript k is limited to the value 1, that is, when the current and the electromotive force are both sinusoidal. Furthermore, the product of the electromotive force and current is not equal to the square root of the sum of the squares of the real power and the reactive power, as defined in either of the preceding ways. Neither is this product the square root of the sum of the squares of the readings of an active and a reactive wattmeter except in those cases where the current and electromotive force are both sinusoidal and the circuit constants do not vary cyclically. The point that I wish to bring out is that while the methods of measurement, as sketched by Mr. Fortescue are sufficiently accurate in most commercial practise, they should not form the basis of any scientific definition of power factor.

F. B. Silsbee: It is most unfortunate that the ideas which electrical engineers have inherited from the single-phase circuit, have become so fixed along the lines of a separate consideration of the several phases of a polyphase circuit, that a very great deal of mental inertia has to be overcome, before the simpler methods of analysis here presented can come into general use. I feel that several more papers similar to the present one will be

required before the metering systems of central stations are changed over to register positive and negative sequence power.

Several years ago a committee was appointed to consider the possibilities of obtaining a definition of balance factor in poly-phase systems, but the inherent complexity of the subject, the lack of realization of the importance of unbalance in some cases, and the lack of familiarity with the symmetrical coordinate method of analysis all conspired to produce a general apathy among engineers which, so far, has prevented the adoption of any definite method for treating unbalanced conditions.

In this and earlier papers Mr. Fortescue has suggested the ratio of negative sequence to positive sequence currents as a definition of unbalance, which would solve this problem. While this definition works out perfectly for the case of 3-wire, 3-phase circuits which, of course, is by far the most frequent case in practise, it seems desirable to have a more general definition of which this might be a special case, but which would cover the more complex cases of 4-wire circuits and those of other than three phases. It seems to me certain that such a generalized definition will ultimately be based upon the symmetrical method of analysis, and I trust that Mr. Fortescue will supply us with such a definition in the near future.

Charles Fortescue: I want to express my appreciation of the discussions that I have received this afternoon on my paper. Professor Karapetoff always adds lucidity to any subject which he discusses. However, I do not agree with him that the commercial application of this principle presents insurmountable obstacles, and this also applies to the next speaker. Mr. Peek seems to think that consumers are so dull that they will not be able to absorb this idea.

Now, I think that the Public Service Commissions and large consumers can take care of themselves very well. They seem to be investigating a whole lot of things, and they seem to be able to get the right kind of talent. I think they will make out pretty well on positive sequence quantities; and as I am quite sure the principle is right, I am sure that it will prevail.

You know sometimes we do not understand a thing because we do not wish to. The average consumer no doubt is quite dull when it comes to a change in his rates which he thinks is going to be in the wrong direction, and he finds it very hard to understand such things as power factor and unbalance factor.

However, if you ride on any train, you will hear them talking there glibly about detectors, multi-stage amplifiers, feed back regenerative circuits, and so forth—they seem to understand those things very thoroughly, so that I think they must be quite capable of understanding such a simple thing as unbalanced kv-a.

However, should there be any possibility that this method will not come into commercial use, nevertheless it provides a means to enable the rate man to arrange his rates so that they are more equitable; so that no doubt you will find it very convenient to make use of positive sequence devices in the laboratory, and in investigating various kinds of loads.

I believe that there is a real application of these principles, and as Mr. Evans has shown, the principle can be applied with standard instruments, commercial instruments that are used every day.

It does not add any complication; in fact, the tendency is towards simplicity, and moreover, certain conditions do occur from time to time in circuits which demand protection for motors, and this principle affords the best means to give that protection.

1. TRANS. A. I. E. E., Vol. 39, p. 1515.

Volt-Ampere Meters*

BY R. C. FRYER,

Assoc. A. I. E. E.
Superintendent Electric Meters, Union Gas & Electric Co., Cincinnati, Ohio

THE point is well known and generally accepted that many things can be done which do not become general practise until the economics governing the practise show that the difference between "cost of doing" and "earnings through doing" is on the proper side of the balance sheet.

The engineer, being a technician, may be a little slow to admit, even to himself, this fundamental; yet engineering development, in terms of actual progress for the good of all concerned, is as fully subject to the immutable law based on this fundamental as is human progress in general subject to other economic and psychological laws.

We in the engineering profession perhaps now, more than ever before, are less ready to admit that any task is impossible, yet we will have to admit that in general our research and development follow the cause of the necessity rather than precede it. This in some respects is as it should be, yet the question arises "Would not this necessity be more often clearly recognized and the solution more promptly offered if it were known that means were at hand for meeting the situation or condition brought about by that necessity?"

The first recognition of the necessity of metering or measuring kilovolt-amperes of alternating currents came through experience to manufacturers of electrical machinery. Many who do not consider themselves as aged can remember when it was common to purchase generators, motors, transformers etc. rated in kilowatts. Due either to the fact that the above machines were often required to carry inductive loads or to the fact that under these conditions controversies regarding the capacity-ratings of electrical apparatus often arose the manufacturers took a wise step and changed their a-c. apparatus rating from a kilowatt to a kilovolt-ampere basis.

At the time this took place the central station industry was carrying a load in which highly inductive apparatus was the exception rather than the rule, and to a large number of central station engineers the full significance of the change was not at once apparent.

During the few years following, which really constituted the "youth" of the central station industry, the effort of the central station was to secure more load, and in the majority of cases very little thought was given to the character of the load with the exception perhaps, of its load factor. Following these years, however, some of the more progressive central stations carrying industrial loads realized that they were purchasing electrical equipment rated upon a kv-a. basis and apportioning the use of same upon a kw. basis. It

became apparent that increased investment was necessary to carry an inductive load over the investment necessary to carry an equivalent non-inductive load. This not having yet become a matter of much importance to many central stations it did not attract general interest and the result was that where steps were taken to remedy conditions, such action was local in application and generally took the form of penalization of the customer operating an inductive load. Being largely local the methods and degree of penalization were varied and largely arbitrary. Perhaps we can not be sure, but it seems that, while these attempts were a step in the right direction, the "penalization idea" was not very constructive. Perhaps these attempts secured a better income on the demand charge of customers operating inductive loads, yet no basic attempt was made by manufacturers in general or by central stations to remove the infection, the result being that with each additional industrial load the condition became worse.

About the beginning of the World War many central stations generated a peak load approaching their kv-a. capacity. Finding it difficult to carry their kilowatt load without exceeding their kv-a. capacity these stations were faced with the necessity of not being able to care for all load offered or of having to enlarge generating and distributing capacity at a time when the capacity was badly needed and yet at a time when capital for same was very difficult to obtain.

This condition stimulated study of the "low power factor" or inductive load question and it was generally admitted that some action was necessary.

Study of the situation brought out the fact that about 75 to 80 per cent of the central station investment lay in the generating and distributing apparatus. It was pointed out that the carrying capacity of the apparatus covered by this portion of the investment was directly limited by the kilovolt-ampere load. From this it became apparent that while no unit of measurement defined central station capacity in terms of 100 per cent investment the unit of capacity applying directly to the greater percentage of the investment was and is the kilovolt-ampere.

Many utilities had given a power factor clause trial in their rates, but finding that this complicated their contracts; finding that many customers could not or did not understand its application; finding that most customers did not see the justice of that which they termed "penalization for low power factor;" finding they were unable to directly meter the factors involved and that the human element largely entered into calculation methods and finding that the return given a customer under "power factor correction clauses" was

*Presented at the Midwinter Convention of the A. I. E. E., New York, February 14-17, 1923.

not a direct ratio to his investment in necessary correction apparatus, many utilities allowed the "power factor clause" to become a "dead letter" in the contract.

Results of the attempts cited above are given space in the T-2-'22 report of the Subcommittee on Power Factor and kv-a. of the National Electric Light Association Meter Committee, which states that of 418 utilities in cities of 20,000 and over in the United States and Canada, 59 show clauses relating to charges in billing low power factored customers. Among these 59 companies there are more than 20 different clauses.

During the last two years this condition of affairs has added interest to the development of

(1) Induction motors to operate at better power factors.

(2) Corrective apparatus (static and synchronous condensers).

(3) Kilovolt-ampere meters.

This has led to more study in proportioning the size of the motor to the load carried, and in obtaining both induction and synchronous motors of the proper voltage rating.

Even isolated stations generating and using their own power have found it economical to employ synchronous apparatus.

The writer recently witnessed a 20,000-kw. load in a large rubber mill near Akron, Ohio, operating at 98 per cent power factor. This was secured largely through the unusual practise of using synchronous motors specially designed for operation on rubber mill drive.

It is of course understood that at unity power factor the ordinary induction watt or watt-hour meter will measure volt-amperes or volt-ampere-hours.

It follows that if both the current and voltage fluxes in the meter be held at their proper value and in proper phase relation the meter will measure volt-ampere hours for any power factor, leading or lagging.

Your attention is also called to the fact that if the in-phase and reactive components of a circuit are properly metered the volt-amperes may be known through calculation.

In general, then, any volt ampere meter or volt ampere hour meter must, of necessity, obtain its operation from one or both the above principles.

I desire therefore, to more tersely cover the present state of volt-ampere metering art to divide the types and makes of meters as follows:

(1) Proper phase relation type meters.	Full Range	- The Bodi Meter (Westinghouse) - The Angus Meter (Esterline-Angus)
	Fixed Range	- General Electric Meter - The Lincoln Meter
(2) Resultant type meters	Full Range Indicating	- The Lincoln Meter - The Sangamo Meter
	Full Range Integrating	The Sperti-Blacksmith Meter (Westinghouse)

In the above outline only meters involving the *principle* and not the *practise* are mentioned. Other meters involving the above principles may now be made or may be made in the future.

The Bodi (Westinghouse) meter involves the principle of operation of the polyphase power-factor meter. It has been found that moving coils carrying the current of the circuit measured (or a portion of same) or carrying the potential of the circuit when suspended in the potential field (in one case), or in the field of the current (in the second case) will take such positions that current taken from them may be in phase with the field in which they are placed.

If then such an arrangement of coils is provided the current from it may be led through the current element of a watt or watt-hour meter and if this current is of the proper value the watt or watt-hour meter is caused to register volt amperes or volt-ampere hours. To supply such a current to the potential element of the meter involves some difficulty since the torque tending

FIG. 1—ONE ELEMENT OF THE ANGUS 3-PHASE METER

to change the position of the movable coils with a slight change in power factor is rather small. More torque for such an arrangement may be had by connecting these movable coils in series and thus supplying current of proper phase relation to the current element of the standard watt or watt-hour meter. The difficulty encountered with this arrangement however is that the volt-ampere load of such an arrangement is rather above the secondary volt-ampere rating of standard current transformers. It must be remembered however, that with this arrangement the standard induction watt or watt-hour meter may be used.

The Angus meter employs somewhat the same principle with a slightly different arrangement. Instead of using the standard watt or watt-hour meter a special meter comprising in the case of three-phase circuits two elements (one of which is shown in Fig. 1) are used. The frame *F* is magnetized by the current coils *C* and *C1*. The potential element *A* is so mounted that it may rotate, changing its position with variation in power factor of the circuit. The polyphase winding on potential element *A* produces a rotating field about

its periphery which reacts against and with the current flux, a portion of which cuts the disk D at the points KN . This reaction causes the potential element, therefore, to assume a position such that its resultant flux is in phase with the field produced by the coils $CC I$, therefore, the torque on the disk is proportional to volt amperes. With a rotating disk and a register the meter becomes a volt-ampere-hour meter, since the usual type of full-load adjustment can be supplied.

FIG. 2—ANGUS METER

Fig. 2 is an assembled view of the Angus meter.

As has been stated a standard watt or watt-hour meter may be caused to register volt-amperes or volt-ampere hours if potential of a degree of displacement corresponding to the displacement of the flux due to the current through the meter is supplied. If the degree of displacement of the flux in the current elements of the meter is known the potential elements of the meter may be wound to cause in their magnetic circuit the

FIG. 3—KILOVOLT-AMPERE-HOUR METER

same degree of displacement. Under such conditions the meter will measure volt-amperes or volt-ampere hours over about 22 degrees angular range with acceptably good accuracy. The General Electric kv-a. hour meter of this type is shown in Fig. 4. Since the meter is not a standard watt-hour meter its range is increased by the addition of another shaft and necessary special potential coils on the required elements.

Both shafts are connected to one register through an overrunning clutch in such a way that the shaft which is running fastest is carrying the register. Such an arrangement practically doubles the range of the single shaft meter.

To change the range of operation beyond the 22 degrees angular range for which one set of elements is built it is necessary to add another rotor and elements or change the windings of the potential elements in use.

In Fig. 3 is shown the Lincoln type VAD transformer and the Lincoln thermal, volt ampere demand meter. This is a fixed range instrument, but unlike the instrument just previously described the displacement of the potential flux does not take place in the meter itself, but is secured by picking up the desired taps supplied on the small auto transformer provided for the meter. The range of the meter is thereby

FIG. 4—3-ELEMENT AMPERE HOUR METER

increased since the change necessary in widely varying power factors can be more readily made, although it must be remembered that the change is to be manually accomplished.

Mr. Paul M. Lincoln has also worked out other ideas in volt-ampere measurement which have been proved, but which are not on the market. It is understood that patents on these are held by the Westinghouse Company for the United States. In one of these meters Mr. Lincoln provides for the movement of two arms—one proportionate to kilowatts and the other proportionate to reactive volt-amperes.

These two arms are attached to a common point, the resultant movement of which is proportionate to the square root of the sum of the squares of the movements of the kw. and r. kv-a. arms, therefore, the movement of the common point is closely proportionate to volt-amperes.

In one arrangement Mr. Lincoln carries the resultant motion to a rotating member engaging a disk rotating at a constant speed. The value of the resultant

determines the distance from center at which the rotating member engages the disk, thus the volt-ampere value is integrated. If this were a practical arrangement it would seem to be ideal, since he obtains a value proportional to the integrated square root of the sum of the squares.

The Sangamo Company is producing in Canada its watt-hour meter combined with the Lincoln volt-am-

FIG. 5—KV-A DEMAND AND KILOWATT HOUR METER

pere demand meter as described for use with phase shifting transformer. Combining as this instrument does a registration of kilowatt-hours and volt-ampere demand it is said to be meeting with hearty approval in Canada. Last years report shows some 1500 volt-ampere-demand meters in use in Canada.

Possibly the latest volt-ampere-demand meter on the market is the Sperti-Blecksmith meter being manu-

are proportional to $r \cdot kv\text{-a-h}$. The shafts are connected to two arms operating a pantograph, the centre point of which is connected through a flexible lead to the kv-a. demand indicator which indicates the resultant value of the in phase and reactive components—i. e. the square root of the integrated kw. and $r \cdot kv\text{-a}$. for the interval of time for which the meter may be designed. Further details of operation are shown in Fig. 6.

The reactive meter is so connected to the pantograph that its integrated value is constant in direction for all ranges of power factor, leading or lagging; therefore the standard meter elements are operative over 100 per cent range in power factor. The inherent errors are small, and being constant in progression have easily been cancelled so that the meter compares in accuracy well with the standard watt-hour meter.

It is seen from the foregoing that quantity production on volt-ampere, volt-ampere-hour or volt-ampere-demand meters merely awaits a consistent demand.

Several large utilities have made, are making and are arranging to make contracts on a volt-ampere-demand basis.

It seems safe to assume or predict that during the next few years the volt ampere or "kv-a." meter will have taken its deserved place on a plane equal at least to the present kw. demand meter.

Discussion

P. A. Borden: I am pleased to see Mr. Fryer's reference to the advances which have been made in the use of volt-ampere meters in Canada, with particular reference to the Lincoln instrument. The Hydro-Electric Power Commission of Ontario, with which I am connected, is probably the largest user of the Lincoln meter, either with or without the so-called V.A.D. transformer. The Commission and the 300 municipalities to which it supplies power for resale use a large percentage of the number of these meters manufactured in Canada, and I may say that both those who sell and those who buy power as metered by this method seem satisfied with the principle as well as with its practical working out.

The combination meter, to which Mr. Fryer has referred as being developed by the Sangamo Company in conjunction with the Lincoln Company is, to date, I believe, a wholly Canadian product. A sample of this device is at present undergoing tests in the Commission's Laboratories. It combines a poly-phase watt-hour meter and a Lincoln demand element, phase shifting for the latter being arranged for three different ranges of power factors, covering everything from about 40 per cent to unity with a theoretical error of less than 2 per cent. In this meter no attempt is made to integrate the volt-amperes. The integration is performed solely on a watt basis; while demand may be determined on either a watt or a volt-ampere basis, as desired.

A brief description of an ingenious volt-ampere meter developed some years ago by Mr. H. S. Baker may here be of interest. In some points this meter is not unlike the present volt-ampere meter produced by the Esterline Company, but it was in regular use some years before anything was published in regard to the latter instrument. Referring to Fig. 1, (which for purposes of clearness is shown as for a two-phase circuit,) we have first an element, consisting of the fixed coils, 1,1, and 2,2, together with the movable coils 3 and 4, thus constituting a power-factor meter. The rotatable element is normally in neutral

FIG. 6—DIAGRAM SHOWING ACCURACY OF KV-A. METER

factured by the Westinghouse Company. The actual construction of this meter is shown in Fig. 5. As shown the meter is designed to register kilowatt-hours and 15 minute block interval volt-ampere-demand. The meter uses standard watt-hour current and potential elements, —no special windings being required.

The rotation of the two right disk are proportional to kilowatt-hour and the rotation of the two left disks

equilibrium, and, consisting, as it does, of a polyphase winding in a polyphase field, will tend to take a position about its axis, representing the power-factor of the circuit, according to the "Second Definition" of the Institute.

The moving part, however, has another function. It will be noted that the equatorial plane of this part does not coincide with that of the fixed part, and that the moving part is free, not only to rotate about its axis but to shift in the direction of

FIG. 1

that axis. It may easily be worked out that, the element having rotated into the position which represents the power factor of the load, the vertical thrust on the shaft will represent the value of the volt-amperes.

As shown in the diagram, this thrust is balanced by a counter-weight on a scale beam. In actual practise the beam carries contacts, which, through a relay mechanism, similar to that of

the Westinghouse graphic instrument, produce an indication on a scale or chart. At the same time, by attaching a pointer to the moving element it is possible to directly read the power factor on a horizontal scale concentric with its axis. And if the moving element be locked from rotating, in the position corresponding to any chosen power factor, the instrument reads volt-amperes at that power factor; so that if it be locked in the unity position the device becomes a wattmeter. This scheme has been in use on the circuits of the Ontario Power Company since 1917, measuring some very important loads, and has proved of great value.

Charles L. Fortescue: An accurate volt-ampere meter is very necessary for the actual determination of unbalanced factor; and I have been watching this development of volt-ampere meters with a great deal of appreciation.

I think that the balance method of measuring power, the balance factor will require a simpler device than volt-amperes on a polyphase circuit, as measured in the ordinary way, so that ought to help a little bit.

R. C. Fryer: I think the conclusions that might be drawn are these: That considerable progress has been made in the solving of the relation of power factor to the rate question. That considerable progress is being made towards the correction of poor power factors, and that the metering engineers in the industry stand prepared to offer practically any device that is desired for the measurement of volt amperes, whether it is taken by the first or second definition. The actual placing of the apparatus in use is now taking place. Several companies are actually using kv-a. meters in their billing department. We will have to recognize the fact, of course, that the practise will not, for a long time, become general. The reason I think is this: That a great many contracts are made on a five or ten-year basis, especially for the interchange of power. The result is that these contracts must run their life, before they can be changed, and those that are in a position to change contracts now are so doing. Canada, it seems for some reason, has been a little bit more forward than the United States, in this direction at least.

only where no a-c. is available as would be the case with a test on a moving electric car.

The operator may quickly change from correct connections for a-c. operation of lamp, trip-magnet, motor, etc. to 6 volt d-c. operation.

d-c. This element will give nearly 3 inches deflection on a 100-millivolt shunt. This makes it possible to use a standard meter-shunt, when taking slow films, and thus obviates carrying a 500 millivolt oscillograph shunt for tests on huge reversing motors, etc. The

FIG. 3—DIAGRAM OF SUPPLY CIRCUIT FOR LAMP, MOTOR, ETC.

A complete *diagram of circuits* and a key for operating the same is moulded into the inside surface of the element-control panel-cover. This is shown in Fig. 3.

The three complete sets of *element resistors* and dial switches (Fig. 2) are extremely convenient for adjusting the elements so as to give any desired deflection. The upper dial, of each set, has a range from 0 to 100 ohms for e. m. f. below 10 volts and for use as a deflection adjuster when the element is used, with a shunt, as an instantaneous ammeter. The lower dial is used to limit the deflection when it is desired to record the instantaneous values of e. m. f. above 10 volts. This dial has a range from 100 to 10,000 ohms. This permits the recording of a d-c. e. m. f. of 3000 volts, peak. Since the sensitivity of the standard element is 0.10 ampere per inch deflection, this would mean a 3 inch deflection on the ground glass, or on the film. The *super-sensitive element* requires but 0.02 ampere per inch deflection and hence will give about 3 inches deflection, with 10,000 ohms series resistance, on 600 volts,

super-sensitive element will not respond to as high frequencies as the standard element. The former has a natural period in air of approximately 3000 cycles per second, while the standard element has a natural period of approximately 5000 cycles, at usual tension and

FIG. 4—THREE-ELEMENT GALVANOMETER. SEPARATE ELEMENT AND CELL TO ONE SIDE

sensitivity. The ultimate tensile strength of the vibrator ribbons is very high (approximately 160,000 pounds per sq. inch) and hence permits a greater tension on the ribbons when it is imperative to have a higher natural period, at a sacrifice in sensitivity.

The refinements in the *three element galvanometer*, Fig. 4 have made it most reliable. The overall dimensions have been reduced and the test increased to over 10,000 volts between each element. The increase in sensitivity is not due to sacrifice in natural period but to the efficient design of the magnetic system.

The novel method of controlling transients, on the first portable outfit, proved to be so reliable that it was incorporated in the final instrument. Further advantage was taken of this method by designing a daylight-loading film-holder. Such would have been useless with former controls, which do not place the transient on a predetermined part of the film, for the daylight-loading roll-film cannot cover the full circumference of the rotating drum.

FILM HOLDER

The daylight-loading film-holder, Fig. 5 is the latest development of the whole outfit and now operates reliably with all standard No. 3-A "Kodak" roll-films. The novel features of this film holder proved to be most satisfactory. A light-tight door in the stator gives access to two doors in

FIG. 5—ROTATING VIEWING, MIRRORS AND DAYLIGHT-LOADING. ROTATING FILM HOLDER.

the rotor. One rotor-door carries the unexposed film-spool, between clips. This door is snapped in place with the unexposed film within the rotor. The initial opaque paper is drawn two-thirds the way around the rotor and its end inserted in the empty spool which is to receive the exposed film. The second inner door is then closed and the stator door also. By the simple twist of a cap, as it is removed, the rotor may be locked in proper position for turning the spool, by an external winding-key. To perfect the action of this film-holder, it was found necessary to turn the spool so as to reverse the curvature of the film and thus keep the film, as well as the opaque paper, tight on the drum. The exposure number, on the opaque paper of the standard film, may be observed through the opening in the stator and rotor made by the removal of the cap. After each setting of the film, the cap is replaced and the rotor is free to turn at any speed desired. After the oscillogram has been taken, the cap is again removed and the film turned to position for the next exposure. The rotor is $4\frac{3}{4}$ inches in diameter and is so designed that the film comes very close to the optical slot of the

main oscillograph case. This permits a much greater angle of convergence of light from the cylindrical condensing-lens. This has made possible an optical efficiency 250 per cent of that of former outfits. With a standard No. 3-A ($3\frac{1}{4}$ in. x $5\frac{1}{2}$ in.), 6 exposure, roll-film, one may take six oscillograms $3\frac{5}{8}$ in. wide and 5 in. in effective length, or three oscillograms 10 in. in effective length. The total length of film after cutting, is more than eleven inches, for the standard oscillogram. Thus prints are correct in length for filing with standard $8\frac{1}{2}$ in. x 11 in. report paper.

VIEWING ATTACHMENT

A rotating-polygon of mirrors, Fig. 5, is added to the outfit for viewing recurrent a-c. phenomena. The mounting of these mirrors is so designed that they are operated from the standard driving-head at the proper speed to cause the waves to float slowly by, or stand still, as the tension on the belt of the induction motor is slackened. Since the incandescent lamp requires no attention, and since the optical efficiency of this instrument has been increased 150 per cent over former outfits, it is possible to operate this visual attachment continuously (without attention) and observe any chance momentary change in wave-shape, due to harmonics introduced to the line. The waves are so bright that several people may observe them at the same time, in an undarkened room. A mirror may be placed above the attachment at 45 deg. and thus shift the plane of vision from the vertical to the horizontal. These features make the attachment particularly valuable in classroom work.

For commercial work the photographic record is always required. The simplicity of operation, with the incandescent lamp and daylight-loading film-holder, makes it easy for the student, as well as for a trained operator, to take oscillograms. An oscillogram must always be taken to show transient (non-recurrent) phenomena. With this instrument it is very easy to obtain excellent records of transient phenomena, well spread out on the film.

PHOTOGRAPHIC OPERATION

The general scheme of photographic operation is best understood by reference to the diagram, Fig. 3. For actual construction see Fig. 1 and Fig. 6. The *contactor*, on the film driving-head, is set so as to operate the *trip-magnet* a fraction of a revolution ahead of the opening of the *mechanical shutter*. This fraction of a revolution is timed to be equal to the lag in operation of the remote controlled apparatus. (The setting of this contactor is immaterial when recurrent a-c. phenomena are being photographed). The *lamp-control switch stop* is set at the $3\frac{1}{2}$, 4 or 5-volt position for slow, medium or fast films, respectively. The control switch is first brought up to the 3-volt position, allowing the lamp to come up to normal brilliancy and is then thrown against the stop. This makes a connection through the contactor to the

trip-magnet thus operating the *remote-control switch*. After the remote control, of the apparatus under test, has started to function, the shutter opens at the beginning of the active film. The transient starts, immediately afterward, and makes its record on the film, by the proper functioning of the galvanometer and optical systems. One revolution after the shutter opens, it

FIG. 6—DRIVING HEAD, SHUTTER MECHANISM, REMOTE-CONTROL SWITCH, AND LAMP-EXTINGUISHING SWITCH

closes and knocks open the *lamp-extinguishing switch*, thus saving the lamp for hundreds or thousands of such operations. Thus the lamp may be on $3\frac{1}{2}$ volts for many minutes taking a slow film, or may be on 5 volts for 0.02 second when taking a film running at a speed of 1000 feet per minute. (0.005 sec. per inch). A good film can be taken, of 60-cycle waves, with the film running at 1300 feet per minute, using the incandescent lamp and the induction motor, in the second belt position.

MOTOR

The instrument is supplied with an *induction-motor* for driving the photographic-film and viewing-mirrors. This gives most satisfactory results equipped, as it is, with step pulleys and back gears. For any one belt

FIG. 7—SIX-VOLT SHUNT MOTOR WITH FIELD RHEOSTAT AND PULLEYS FOR OPERATING FILM ON ISOLATED TESTS

position, the *film speed is very constant* and can be relied upon to within a fraction of one-per cent, when operated at a given frequency of supply. Where no a-c. supply is available it is easy to obtain a *small six-volt shunt-motor* to operate the film. Fig. 7 shows such a motor equipped with step pulleys and a field rheostat. The field is normally supplied with 6 or 12

volts and the armature with 2 or 6 volts, depending on the range of speed desired. An additional pulley may be supplied to go on the end of the a-c. motor-shaft so the backgears may be used for great reductions in film speed. This is convenient for *studying actual operating conditions* of electric elevators, subway trains, steel-mill motors, etc. This range of 0.2 foot per minute to over 1000 feet per minute, film speed, covers practically all requirements for the standard film and is a big advance over previous outfits.

A detailed description of the shutter mechanism and of the variable shunt (with a range of 20 to 1000 amperes continuous and 25,000 momentary) will not be repeated here since it would be the same as for the original outfit.

LONG FILM ATTACHMENT

A slow-speed, long film, daylight-loading attachment, Fig. 8 has been developed for certain fields of works. This is readily attached to the standard outfit and makes it possible to take any number of oscillograms, 58 inches in length, *without resort to a darkroom*. The film speed is remarkably constant over the whole length. On the first test-run, a slow belt-

FIG. 8—LOW-SPEED, LONG-FILM HOLDER, OPENED UP AND ASSEMBLED

position, and the back-gears of the induction motor, were used to give a total exposure of over five minutes. With the belt tight, the record was so uniform that each individual cycle could be counted on a 25 cycle wave, even though they were less than one hundredth of an inch apart. This special holder was repeatedly loaded and unloaded on a destroyer while the latter was rolling and pitching as it plowed through a stormy sea.

This film-holder is quite novel in its operation. A standard 10 exposure #3-A "kodak" film is used. Split, flanged pins are plugged into the ends of the spools so these extensions fit into vertical slots in the holder with the unexposed film below a main driving drum, $1\frac{1}{2}$ inches in diameter. The film raps half way around this drum and is wound up on another spool just above. Two rollers, one below the unexposed spool and one above the exposed spool, are drawn tight against the

opaque paper, on the spools, by flexible (spiral-spring) belts working in pulleys beyond the ends of each roller. The lower roller tends to hold back the unexposed film while the upper roller ensures the proper winding of the exposed film. Due to the fact that the upper pulleys are slightly smaller than the lower pulleys, all creepage is compensated for, and the film keeps the same peripheral velocity as the one driving drum. A red observation window permits the operator to note the numbers on the film as the exposure progresses. The holder is easily loaded and unloaded on the oscillograph without fogging the film. The films may be developed by any photographer or by the operator at his convenience, either in a dark-room or in a "kodak" tank-developer. This film holder is much better for low-speed work than the standard rotating-drum, as it gives nearly six times as long a record and

FIG. 9—TYPICAL OSCILLOGRAMS TAKEN WITH PORTABLE INSTRUMENT

thus shows up the details of operation of reversing-motors, electric trains, electric-arc furnaces, maneuvering of submarines, etc. Long films have been taken with a total time of 45 minutes. This may be made still greater if the case demands.

VENTILATION

Even though the various parts occupy a very small space adequate ventilation is provided. The resistance units are wound on thin cards of micarta so as to be very nearly non-inductive and so as to present a relatively great radiating surface. Over 1700 square inches of radiating surface is provided for the 30,000 ohms of resistance. Openings below and above these cards allow good circulation of air. Practically the only continuous operation that they would be subjected to would be the voltage from the secondary of a potential transformer. This would mean but 10 watts per element resistor. At ten times this input no appreciable heating is noticed.

The galvanometers in the first units were of an improved electromagnet type and were very satisfactory for an electromagnet equipment, occupying less space, consuming less energy and being insulated for a higher voltage between elements than any previous 3-element unit. The very latest developments, however, have brought out a superior magnet, of a *permanent* type, which gives even better sensitivity to the same vibrator elements, and eliminates: the field coil, rheostat, am-

meter, battery, rectifier, bus-bars, etc., which were formerly required for the electromagnet galvanometer. This simplifies the diagram shown in Fig. 3 and greatly improves the instrument. These features insure cool operation of the damping fluid in the vibrator well and thus minimize the errors due to a change in viscosity of the damping liquid. This cool operation, together with the fact that the walls of the wells are made of micarta (with no coloring matter), minimizes discoloration of the damping fluid and thus prolongs the optical efficiency without attention.

AUTOMATIC OPERATION

Any number of these instruments may be operated *simultaneously*. Each oscillograph may be in a different substation and show the local effect of the same short-circuit. The novel features, of this instrument make it possible to connect its supply (for motor, lamp

FIG. 10

and trip-magnet) to a quick-acting relay, in the secondary of a current transformer in a high-voltage power-system, so that the oscillograph will function perfectly on a *chance short-circuit* (or heavy over-load). The record will show the unreduced value of the short, the arcing voltage, the current interrupted by the breaker and the restored line conditions. This remarkable action is made possible by the automatic, quick-acting features of this oscillograph. With no series resistance in the lamp circuit, the filament will come up to abnormal brilliancy in less than one-tenth of a second due to the great initial rush of current through the filament (the cold resistance of the filament being less than one-tenth the hot resistance). The lamp-extinguishing switch is re-connected, for automatic operation, so that it breaks the supply circuit, at the end of the exposure, and thus cuts off the motor, lamp and trip-magnet.

NEW FIELDS OF OSCILLOGRAPH ACTIVITY

From the foregoing description of the new instrument it is easily seen that only a few of its many new possibilities have been utilized. Engineering schools may use such an instrument to solve the many problems arising in small electrical industries, in the mills of the district, in the local electric power plants and transmission lines. This would be good training for post-graduate students and might result in lessening the financial burdens of the institution.

The whole outfit, Fig. 1, may be taken on a Pullman car in a special carrying case (for the main unit) and a handbag (for the motor, film-holder, viewing mirrors and shunt). An operator, assisted at times by the local porter, may personally conduct the outfit to almost any part of the country. A lower Pullman berth gives ample room for both operator and outfit. This is in considerable contrast to the bulk of express crates required to properly transport any previous, truly commercial, oscillograph outfit. In addition to its portability, its independence of any source of power supply greatly increases its range of operation, and its complete independence of a dark room makes its application still more simple. Such features enabled an operator to take two-hundred oscillograms in two days without changing a single optical adjustment. In another case an operator set up the apparatus in an electric car, in a distant city, and took over three dozen oscillograms in one day. The apparatus was set up in the morning with suitable switches to give a score of different combinations of current and voltage, without cutting off the power from the car. Calibrations were made and then the car was put through many maneu-

FIG. 11

vers, in and out of thick traffic. Oscillograms were taken while the car was at full speed, during reversing, braking, acceleration, heavy overload, short-circuit, etc. Each record was of a transient condition and most of the records were made when the car was jerking or jolting, yet the records were as undisturbed as though they were made in a quiet laboratory. Not a single film was developed until after the outfit had been removed and the car put back into service, yet there was not a poor record in the lot, as far as the oscillograph was concerned. During the whole test the outfit was supplied by a battery borrowed from the starting and lighting system of an automobile.

The problems which are studied with an oscillograph are not always fundamentally electrical. Many purely mechanical movements can be detected and studied only through the medium of electricity and the oscillograph. Undesirable vibrations in machinery, noises, minute movements, momentary pressures, disturbances in the atmosphere, properties of materials and many other non-electrical functions have been studied with the oscillograph. Force or movement has to be transformed into a change in electric current through the medium of the carbon microphone, a special generator, a varying capacity or reactance, or the action of the

piezo-electric crystal. The resulting current may be recorded directly by the oscillograph, or first amplified to suitable strength by the three-electrode vacuum tube. It is necessary to study these mechanical problems under operating conditions, and usually far from any electrical laboratory.

The instrument makes easy the solving of inductive interference troubles in distant telephone lines, and, in fact, makes it easy to study the actual conditions under which any piece of electrical apparatus is operating no matter whether that apparatus is in a well equipped laboratory or in some other part of the country, far from any laboratory convenience.

SUMMARY OF THE SPECIAL FEATURES OF THIS OSCILLOGRAPH INSTRUMENT

1. Complete in one micarta case, 11 x 11½ x 25 inches over all, except for film holder and motor.
2. May be supplied by 110 or 220 volts at from 20 to 70 cycles a-c., or from a 6 volt storage battery, for field operation.
3. Shutter mechanism and remote control switch which place transient phenomena on desired part of fast film.
4. Improved optical efficiency and an incandescent lamp illuminant, operated at momentary abnormal voltage, so as to take fast oscillograms.
5. Included transformer, for supplying lamp and motor.
6. Very compact and well insulated 3-element galvanometer.
7. Element resistances and control to cover the broadest range of commercial testing.
8. Film, holder using standard roll film requiring no dark room.
9. Weight of complete outfit, 100 pounds.

Discussion

J. R. Craighead: The oscillograph shown represents a combination of elements which have been considered necessary for oscillographic work under most conditions. There is a distinct advantage in getting as many of these as possible into a single device, and making that device as nearly portable as possible.

The statement made by Mr. Legg, that by the development of this portable device, Oscillographs can now be used everywhere, rather implies that they could not be used everywhere before.

Now, "everywhere" is a pretty broad term, and I do not happen to have any personal experience that goes quite that wide; but I have known of satisfactory work done with oscillographs in factories, foundries, mines, battleships, destroyers, out-doors in the rain, out-doors in tents, and in various conditions where it would seem that a limited laboratory device would be impracticable. The gain from the development under discussion, is not so much a gain in the field where the oscillograph can be used, as it is a gain in the convenience with which it can be transported to that field, and applied, when it is brought there.

In developing this device, considerable attention has been applied to diminishing weight. I have checked up as nearly as I could the elements contained in this device, which is stated to weigh 100 pounds. The latest oscillograph, with full-sized corresponding elements separate from the oscillograph, weighs about 145 pounds. That is a very distinct gain. It is worth

lower price. For laboratory work it is not necessary to have the control elements self-contained and a very simple outfit consisting of a single vibrator with the simplest kind of shutter and film drum device would meet the requirements in many cases. There is no such instrument upon the market at present and it would appear to me as though it would be extremely useful for smaller institutions and as an auxiliary to the more complete oscillographs for the larger institutions.

J. W. Legg: The latter part of this discussion has, to a considerable extent, cleared up some of the questions brought out in the first part.

The paper shows that expansion of oscillography requires more than portability; it requires greater completeness of equipment, greater permanency of adjustments, greater reliability, and greater independence of power supply. The instrument described has all these improvements, and may be transported, as shown by Mr. Borden's discussion, at from one-fifth to one-eighth the weight of previous apparatus of comparable value.

I believe the 145 pounds weight, claimed for previous apparatus, does not include any such resistance as 30,000 ohms. The figure is nearer 4000 ohms. Neither does it include a two-kw. motor-generator set, or bulky 110-volt storage battery, one of which must be obtained if no constant voltage, d-c. power-circuit is available to supply the older oscillograph outfit. The new outfit will operate from any a-c. lamp socket, or from a six-volt storage battery.

The paper states that the 3000 volt d-c. circuit is the exception which cannot be handled by the oscillograph continuously, without external resistor. A 3000 volt peak is very common during switching operations in a 600-volt inductive circuit. The internal resistances of the oscillograph will handle this peak, very nicely, for electric railway tests. The whole 30,000 ohms may be used with one element, without overheating, for recording 3000 volts applied for half an hour or more. Long application of high voltage is seldom required, as control switches may be used to throw on the 3000 volts shortly before taking an oscillogram, and disconnect it immediately after.

Another reason why heating will not be as great as expected, in this oscillograph, is that the vibrator element requires less current per unit deflection, than previous makes, and hence there is less heat given off in the resistors. After four years experience with the included resistors, no undue heating has ever been encountered in commercial testing.

Formerly a day's delay was often caused by the necessity of fixing up a suitable dark room for developing, and reloading film holders. A portable dark room was sometimes carried into the field for these film holders. This added to the already large shipment of carefully packed apparatus. Now we take as many as a hundred oscillograms without resort to a dark room, and then turn them in to the town photographer to develop after the test is over. This daylight-loading feature of the new film holder, surely helps to expand oscillography.

In regard to the remote control of transients; high-speed films are generally required only with quick-acting switches, and slow-acting switches generally require longer exposure films. Such cases are very easily handled with the remote-control device incorporated in the oscillograph. High-speed closing switches may operate in a few thousandths of a second. With the film traveling at 1000 feet per minute the control mechanism may be started seven-hundredths of a second before the opening of the shutter, if desired. Even an ordinary contactor will close in this time, if it is set somewhat closer than usual. Heavy switches, such as oil breakers in high voltage lines, are more sluggish in action, both electrically and mechanically. In order to show the complete electrical transient, the photographic drum must be run much slower. Thus the oscillograph mechanism has ample time to operate the large switch and still cause the transient to appear on the proper part of the film. In case a higher-speed film is required, to study the first

part of the short-circuit transient, then the large oil switch may be blocked up so as to be nearly closed, and thus greatly reduce the time required for the magnet to completely close the switch.

Automatic operation, on chance short-circuits, will show the a-c. wave before it is reduced by any breaker action. An actual record is not made of the first a-c. peak, but this maximum peak may be estimated by projecting back the wave according to general laws of transients. In most such tests, the manufacturer is most interested in the characteristics of arc rupture in the oil breaker. These are clearly shown on the oscillogram. The first discernable cycle may be somewhat crowded, due to the fact that the film motor may not be fully up to speed, but this is no material handicap in studying the film.

The problem of keeping the mirrors bright and clear was taken up ten years ago by the Westinghouse company. This company has made mirrors ever since, with considerable improvement in optical efficiency and permanence. One of the vibrators in the first portable oscillograph was not taken from its well in over a year of travel and testing, yet it was just as good, at the end of that time, as a freshly applied mirror on the adjacent vibrator. This is due, partly to the fact that the galvanometer remains at room temperature and hence does not discolor the damping-fluid, partly because the well is made of clear duck-micarta and does not react with the damping-fluid, and partly because a certain clearer damping-fluid may be used since it remains at room-temperature.

At greatest abnormal voltage, the incandescent-filament lamp is operated at the melting point of tungsten, but practice has shown that it is not materially harmed at this temperature provided the application of excessive current is short enough. It is fully up to temperature, as shown by the fact that the beginning of the oscillograph record is just as intense as the end. A continuous half second at this maximum temperature would destroy the filament. Unless a complete quartz optical system is to be used, the writer cannot see any great advantage to a tungsten wire in open air.

A vibrator mirror is not very large in comparison with the vibrator ribbon itself. Hence, as the vibrator ribbon does not introduce appreciable damping, by eddy-currents, it would not seem reasonable that an aluminum mirror would add damping enough to replace the damping-fluid. When the wells are made slop tight, the damping-fluid detracts little from the portability of the outfit.

Mr. Dellenbaugh greatly exceeded the advertised speed limit by taking transient phenomena with a film speed of 2500 feet per minute, with the help of the great optical efficiency of this instrument, and the application of a d-c. arc-lamp. Such a speed is not recommended, as it required special adjustment of the shutter mechanism for this unparalleled film-speed with high-speed transients. A film speed of 1250 feet per minute is often used by the manufacturer. At this speed the incandescent lamp gives abundant light to show up transient phenomena with the main amplitude varying from 3000 to 6000 cycles per second. Only an experienced operator could expect good results at these speeds.

To prevent reflection from the sky, or white ceiling, it is well to place a mirror above the viewing attachment at an angle of 45 deg. This will enable many people to observe simultaneously if they are seated in line with the inclined mirror.

The writer has designed a six-element oscillograph which is even smaller than the three-element model just described. This is to be used for three-phase tests on transmission lines and oil switches. Hence four sets of 5000-ohm resistances and four of 50 ohms is sufficient. The outfit is to be operated on six-volt storage-battery only, and hence has no included transformer. These modifications, and the extremely compact construction of the new permanent-magnet galvanometer-elements, has made it possible to get this complete six-element outfit in a case 9½ by 11 by 25 inches over all, except for the six-volt motor and the film-holder (taking a seven-inch width of standard roll film).

E. E. F. Creighton: (Communicated) I have in mind one point that was brought up by Mr. Legg, namely the credit to those who have been involved in the development of the oscillograph. I do not want to take advantage of this occasion to impose on you any of my personal history, but there are incidents apropos to this discussion, in that they relate to the early development of the oscillograph.

In 1898, I was with Mr. Duddel in London, and saw the progress that he had made in the development of the oscillograph. Shortly afterwards I went to work with M. André Blondel and remained two years. When I arrived in Paris in 1898 he had his oscillograph completely developed. He had both the magnet and bifilar types of vibrators. Without question M. Blondel was the father of the oscillograph. Mr. Duddel did a great deal to improve it.

I brought the first Blondel oscillograph to America in 1900

and used it first at Stanford University and for several years while with the Stanley Company. But when I arrived in Schenectady in 1904 I found a very fully developed oscillograph there. So I have always given Mr. L. T. Robinson full credit for the work that he has done, which is greater than Duddel's in making a practicable, useful device out of the oscillograph,—it is actually the oscillograph as we know it today.

I have used the oscillograph every year since 1898 and having taken many thousands of oscillograms I can answer one question about the mirrors. The mirrors are stuck on to the bifilar with shellac. When the shellac dries it naturally shrinks and cracks, and thereby breaks the continuity of the silver on the back of the glass. Therefore we renew these mirrors periodically, without stopping to make extensive photographic tests to determine whether or not they are in first-class condition. It can be done in just a few minutes,—when you get used to it.

Measurement of Transients

BY FREDERICK E. TERMAN

Leland-Stanford University

Review of the Subject.—The transient crest meter was developed to investigate several pressing problems in high-voltage transients. It consists of a gold leaf electroscope in series with a rectifying device, an electron tube, which enables the electroscope to charge, but prohibits discharge. The charge that is captured in this manner is proportional to the maximum impressed potential, and where adequate insulation is possible, will remain substantially undiminished for many seconds or even minutes after the transient has passed by.

The instrument described is thus seen to be essentially a crest voltmeter. By the proper use of inductance, resistance, and capacitance it is possible to make the applied voltage dependent upon the maximum peak, maximum slope, or maximum area of current and voltage waves, thus giving information regarding the character as well as the size of the transient.

The method of calibration, and the precautions that must be taken in measuring transients with this instrument are pointed out in detail in the paper. In particular, care must be taken to

carefully insulate the gold leaf. The minute charge stored at several hundred volts makes it necessary to employ special vacuum bulbs with the filament and plate leads coming through opposite ends of the tube.

The crest meter has already served successfully in several investigations. The first application was the measurement of the potential of the sphere electrode of a high-voltage oscillator. The method followed consisted in measuring the charging current to the sphere by means of a shielded electroscope resting within this electrode. When combined with a second gold leaf acting as relay contact to give an alarm at a given voltage, the instrument is admirably suited for the study of transmission system disturbances, for the observer need be tied no closer to the test than remain within hearing distance of an electric bell. Such an application was made during four months of the past summer on a 110 kv. line belonging to the Pacific Gas & Electric Company, in an effort to discover the cause of apparently unprovoked flashovers which this particular line experienced from time to time. Other similar applications become evident as their need arises.

PRINCIPLE

TRANSIENT phenomena occur continually in electrical practice, and are often of the most practical importance because of the disturbances they give rise to in electrical circuits. Due to the momentary nature of transients, direct experiment and measurement of such oscillations is unusually difficult, and the choice of methods available for any investigation is very limited.

While studying certain high-voltage phenomena, Prof. Harris J. Ryan of Stanford University found it necessary to develop a new type of transient crest voltmeter. The instrument that was evolved to fill this want can be used to advantage in the investigation of many types of transient oscillations, to determine their nature and magnitude. The following paragraphs give an outline of this meter with the hope that others will find it of assistance in solving their problems.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 14-17, 1923.

Some years ago, Dr. Clayton Sharp¹ described a crest meter used to determine the form factor of low-frequency alternating-current waves. This indicator consisted of an electron tube in series with a condenser, and made use of the principle that the vacuum tube will allow a condenser to charge, but not discharge. The condenser will hence charge to the crest voltage of the wave and hold this potential.

A consideration of the principles involved in such an instrument brings forth the remarkable possibilities of this type of indicator in reference to high-frequency transients. From elementary electrostatics, the voltage across a condenser is:

$$E = (1/C) \int i \cdot dt$$

It is apparent that the factors controlling the time required for the condenser voltage to attain a certain value are the rate of current flow and the amount of current required, that is to say, upon the size of con-

1. Sharp and Doyle, "Crest Voltmeters," A. I. E. E., 1916.

denser used, and the space current of the vacuum tube. In practise the charging rate cannot be greatly increased, since the saturation current of vacuum tubes is at best only a few hundredths of an ampere. Where the time element is very small, as in the case of radio frequencies, it is evident that this low rate of charge lasting only a small part of a second requires a very minute capacitance to build up to the voltage of the transient.

The requirement of a small capacitance led to the adoption of a gold leaf electroscope as the basic unit of the instrument. This arrangement was chosen since a gold leaf electroscope not only supplies a very small capacitance, but also reads the potential of the condenser by the deflecting gold leaf. The capacitance can be very small, in the neighborhood of two millionths of a microfarad being the value for the instruments constructed. This quantity is such that one one hundredth of an ampere flowing for a ten millionth of a second is sufficient to charge the electroscope to five hundred volts. It is obvious that with such minute amounts of energy stored at potentials of hundreds of volts, insulation of the very best must be provided.

Throughout the instrument particular care must be taken in this regard. The gold leaf and its electrode should preferably be isolated by a piece of cast sulphur. Sulphur is chosen, since it can be readily handled, and is an almost perfect non-conductor. In fact the resistance between the gold leaf and the case of one electroscope constructed was several trillion ohms, and a large part of this conductivity could undoubtedly be attributed to leakage arising from surface contamination rather than by conductivity through the sulphur.

A great amount of trouble is experienced in obtaining adequate insulation between elements of the vacuum tube. It is well known that glass gathers a surface film of moisture, a film varying in thickness with conditions, and practically impossible to remove. Due to this factor, a long leakage distance between elements of the bulb is necessary, the ordinary tube with all connections coming out of the same press being practically useless. It was found necessary after some experimentation to employ two element bulbs built especially for the crest meter by the Moorhead laboratories. These tubes have the leads coming from opposite ends, and hence give a one hundred per cent utilization of the possible leakage distance.

Even with such construction certain atmospheric conditions cause the leakage rate to be excessive. To reduce the thickness of the moisture film on the glass to a minimum it is desirable to keep the walls of the electron tube slightly warmer than the surrounding air. In practise this can be gained by covering the bulb with a celluloid hood that prevents convection currents carrying away the heat radiated by the filament. Under normal conditions the rate of leakage per minute will not exceed ten to fifteen per cent of the total charge. For most kinds of work it is possible to

provide a relay that will disconnect the electroscope from the bulb after the transient has passed. Action by the relay makes it possible for the leakage to take place only over the superior sulphur insulation, and hence reduces the rate of loss of charge to something less than one per cent a minute.

The appearance of the electroscopes that have been built is shown in Fig. 1. The method of construction illustrated is both simple and very satisfactory. The case was formed on four sides by bending a long strip of sheet tin into a cube. The edges were flared out as shown, and small wires run across the open ends and soldered in place, forming a complete electrostatic cage with perfect visibility to the interior. To protect the gold leaf from air currents it is necessary to shield the open ends with thin glass plates held in place

FIG. 1—THE TRANSIENT CREST VOLTMETER

by heavy paper pasted over the edge. The sulphur insulation is in the form of a slab fitting on the top of the cube, and supporting the gold leaf on a rod extending through a hole in the metal case. Other details of construction, as well as the celluloid hood, are clearly shown in the photograph, so will not be described further.

The deflection of the gold leaf is read by lining up a thread with the deflected leaf, and determining the thread angle by means of a protractor that is mounted on the electroscope as shown in Fig. 9. An accuracy of about plus or minus a half of a degree can be readily obtained with a little practise. The personal equation enters strongly into the readings of the instrument, and it is preferable, though not necessary, that cali-

bration curves and observations during tests be made by the same investigator.

APPLICATIONS OF THE CREST METER

The crest meter that has been described is essentially a crest voltmeter, but in this capacity its use can be extended to the investigation of other quantities. By utilization of the proper circuits, the crest meter will indicate the *maximum* peak, *maximum* steepness of wave front, and *maximum* area of both voltage and current waves.

A series of such connections for the investigation of current waves is shown in Figure 2. The measurement of peak currents is almost self explanatory. It must be remembered that R should be absolutely non-inductive where radio frequencies are present. Replacing the resistance by an inductance as shown in Fig. 2B makes the voltage indicated by the crest meter equal to the maximum value of $L di/dt$, that is, proportional to the steepness of the wave front. Using a capacitance in place of the inductance gives informa-

FIG. 2—CONNECTIONS FOR MEASURING PROPERTIES OF CURRENT WAVES

tion regarding the area of the wave, since the e. m. f. across a condenser is the time integral of the current flowing in the condenser. Extending the same principles to the study of voltages is a simple matter. Peak voltages can be read either directly or by the use of a potentiometer. Wave fronts and areas can be determined by the applications of the principles illustrated in Fig. 3B and 3C. In these circuits if the impedance offered by R greatly exceeds that offered by L or C , the current through the shunt circuit containing R is an exact replica of the voltage wave in the main line.

In the study of transmission line transients, a potentiometer of the water filled hose type² serves admirably. Fig. 4 shows such a potentiometer used in an investigation conducted on a 110,000-volt line. The power consumption in the hose is about two kilowatts for the complete loop of two hoses in parallel,

² H. J. Ryan, "The High Voltage Potential] Meter," A. I. E. E., 1916.

so by circulation of the water through a wash tube as reservoir, the necessary dissipation of energy can be obtained with a limited amount of water.

The equivalent circuit of the crestmeter is shown in Fig. 5. The electroscope acts as a pure capacitance, the electron tube as a capacitance shunted by a variable

FIG. 3—CONNECTIONS FOR MEASURING PROPERTIES OF VOLTAGE WAVES

resistance. In the proportions existing in the instrument the condenser furnished by the bulb is the smaller of the two by only a slight amount. This brings into consideration certain complications that can affect the accuracy of the results obtained.

FIG. 4—HIGH-VOLTAGE POTENTIOMETER USED WITH CREST METER

An examination of Figure 5 will make this evident. At the crest of a transient the potential of the two elements of the electron tube is the same. As soon as the voltage begins to die away R becomes infinite, the potential of the filament is no longer equal to that of the

plate, and an electric field is set up between them. The energy represented by this field comes from the charge the electroscope possesses, and hence must affect the indication of the gold leaf. Where the final potential of the filament is not controlled, serious errors will be introduced in this fashion.

The remedy is simple, being merely to always keep the filament at a definite potential in respect to the electroscope case when reading deflections. The easiest way of accomplishing this is to connect the two together. This operation makes the variable element otherwise shown in Fig. 6. Throwing the switch one way impresses the known voltage on the instrument, throwing to the other side connects the case and fila-

FIG. 5—EQUIVALENT CIRCUIT OF CREST METER

present become constant at a value easily reproducible. Where connections such as shown in Fig. 2A are used, and there is no current flowing when the instrument is being read, it is obvious that this condition is attained without the special switch necessary under other circumstances.

CALIBRATION

Calibration of the instrument may be readily carried out using direct current, keeping in mind the considerations that have just been presented by using the circuit ment. If the potential is supplied by a generator it is preferable to use a machine with a large number of commutator segments and with steady brushes to

FIG. 6—CIRCUIT FOR CALIBRATION OF CREST METER

reduce the ripple to a minimum. One must remember at all times that the crest meter reads the peak voltage, while the direct-current voltmeter does not.

A calibration of the crest meter incorporating the electroscope shown in Fig. 1 is given in Fig. 7. It is seen that the useful range of this particular instrument is between two hundred fifty and one thousand volts. Above this the curve changes too rapidly to be of very much use. It had been thought that the intense field at the edges of the gold leaf might start ionization of the air at low potentials, but investigation of this point up to twenty-two hundred volts gave no evidence that such was the case. From a comparison of the various electroscopes built, the size of the gold

leaf appeared to be the principle factor determining the sensibility, the general over-all dimensions in other respects having very little direct influence.

The calibration of the electroscope changes from day to day. This variation extends in a similar fashion to the entire range of the gold leaf, and will raise and depress the calibration curve as much as seven or eight per cent at times. Where relative or approximate values are desired this factor does not introduce such serious trouble, but when absolute values are being determined, frequent recalibration is necessary.

FIG. 7—TYPICAL CALIBRATION CURVE

OPERATION OF THE CREST METER

The very sensitiveness of the crest meter is often a source of trouble and error. The peak value of voltage is always read by the instrument, irrespective of whether or not this voltage is the one being investigated. In this connection an interesting discovery serves as a typical example. A circuit such as shown in Fig 8. was being used to study damped oscillations. From the connections it would appear that the voltage read by the crest meter after charging the condenser and closing its switch would be equal to or less than the

FIG. 8—A CIRCUIT WHICH SET UP UNEXPECTED TRANSIENTS THAT WERE OBSERVED BY THE CREST METER

charging potential, but the result was actually three to four times this value. Analysis of the factors involved gave the explanation of this unexpected result. The circuit comprising the electroscope, electron tube, and leads, made a series circuit of inductance and capacitance to which was applied an instantaneous voltage upon switching in the condenser. It can be shown that under these conditions large voltages of extreme frequencies will exist over parts of the circuit, exactly as the crest meter indicated. This is merely cited to show how apparently unreliable results merely verify the integrity of the instrument as an indicator

of crest voltages. It was found that such resonance phenomena did not occur when the instantaneous voltage was supplied by generators instead of condensers, apparently the inductance of the machine windings preventing the rapid mobilization of energy possible in the condenser discharges.

A number of possibilities of the crest meter idea will occur to the engineer. An electrostatic voltmeter can be used to replace the electroscope, although a considerable increase in capacitance results which will render

FIG. 9—SHIELDED CREST METER, WITH WINDOW TO INTERIOR OPEN

FIG. 10—SHOWING ADDITIONAL GOLD LEAF ACTING TO CLOSE A RELAY CIRCUIT

the instrument unfit for the most rapid transients. It must be remembered, also, that the crest meter as described can only work on one-half of the wave being investigated, due to the unilateral conductivity of the vacuum tube. Where it is suspected that positive and negative crests are different, two such instruments connected back to back must be used. Fig. 9 shows a useful form of the instrument for the investigation of currents flowing in parts of a high-voltage circuit. Being self-contained, and completely shielded by copper

gauze, the crest meter may be raised to any potential above ground that is convenient.

In the investigation of infrequent surges it is advisable to incorporate a relay in the test outfit. By placing an additional gold leaf in the electroscope arranged as shown in Fig. 10 in relation to an adjustable contact, a relay capable of handling sufficient current to throw a polarized relay results. The polarized relay can operate any number of circuits, which may perhaps ring a bell, short-circuit the filament of the tube to the electroscope case, and then disconnect the tube altogether from the electroscope to reduce leakage, and so on.

By carefully providing protection from dust, dirt, and dew, the electroscope will serve very well for field use. Fig. 4 gives a picture of the arrangement for a ten-day, two-hundred-and-forty-hour test on a 110,000-volt power line. In such open conditions it is always necessary to keep the actual crest meter inclosed to protect it from dirt, spider webs, etc.

SUMMARY

The electron tube-condenser type of crest meter affords a means of investigating the character as well as the size of transients of extremely short duration. In order to accomplish this, certain precautions in construction and operation must be observed. Of particular importance is the capacity and insulation of the condenser, and the filament potential at the time of making a reading. The final instrument is suitable for the reading of *maximum* height, area, and steepness of current and voltage waves with considerable accuracy. Its readings are readings of maximum disturbances occurring, and if unsuspected oscillations of a greatly different frequency exist side by side with those being investigated, the crest meter can only be expected to give an indication of the largest disturbance. For this reason it requires an apprenticeship before reliable results can be expected. The application of the transient crest voltmeter is largely limited to laboratory and research work, but by proper protection from disturbing elements it is available for field service.

The writer wishes to give special acknowledgment to Prof. Harris J. Ryan in connection with the transient crest meter. He is the originator of the instrument, and took a constant and most helpful interest in the work that was performed with it.

Discussion

E. E. F. Creighton: We have had so much difficulty with large spark lags in vacuums that I should like to ask Mr. Terman a question about his measurements. We have found in all sorts of vacuums a considerable dielectric spark lag and he has, I know, tested this with an oscillator where the duration of discharges can be expressed in thousandths of a second. But I should like to know if he has tried out the spark lag, using a frequency say of about five million cycles per second, and a single discharge.

F. S. Dellenbaugh, Jr.: Mr. Terman's device for mea-

asuring transients should prove a very valuable addition to the instruments for measuring electric conditions which exist for extremely small periods of time. In the Massachusetts Institute of Technology Research Laboratory a good deal of work is being done investigating transient conditions upon smooth artificial transmission lines. If the artificial line, or any line for that matter, is long, the duration of the transient occupies sufficient time to be measured by an oscillograph with a vacuum tube repeater where drawing power would distort the conditions. However, a great many cases arise where short lines with extremely rapid transient oscillations require investigation. Usually the maximum voltage is the point of most interest as one of the chief dangers of transients lies in the rupture of insulation. For this type of investigation the Terman crest meter is ideal. Under those conditions it would also appear possible to use an instrument such as the Compton electrometer instead of the goldleaf electroscope which would somewhat increase the accuracy of the readings providing the transient existed for a long enough time to charge the electrometer.

In Figs. 2 and 3 of Mr. Terman's paper he shows the crest meter connected to an inductance in case *B*. This would not always give the steepness of the wave front, since the penetration of a wave into the inductance depends upon the distributed capacity present. If the inductance were free from distributed capacity then a vertical wave front would be completely reflected and the crest meter would show no reading at all, while the rate of change of current immediately adjacent to the inductance would be really infinite.

F. E. Terman: Integrity tests of the transient crest voltmeter under severe laboratory conditions have given no indications of a dielectric lag which Mr. Creighton refers to as playing an important part in many vacuum discharges. Considering the mechanism of current flow in a vacuum tube it is evident that the conditions are hardly comparable to those involving a spark. The ever present electrons surrounding the filament begin to move as soon as the electrostatic field is established between filament and plate. This occurs with the velocity of light, making the only lag that arising from the time required by the electron in its travel to the plate, which a short computation shows to be entirely negligible, even for frequencies in the order of many millions.

Certain experimental results verify this reasoning. Thus with the transients referred to in connection with Fig. 8, which were in the order of tens of millions of cycles per second, it was found that when the filament temperature was sufficiently low the electroscope was unable to charge fully on one transient, in contrast with the result accompanying high filament emissions. All evidence obtained pointed to limitations in space charges as

the important factor governing speed of operation. Some other experiments not described here, in which travelling waves on a twenty foot pipe were partially reflected by a water column potentiometer gave results for the voltage at the water column which indicated that the crestmeter indications were reliable under these conditions.

Prof. Dellenbaugh points out an important fact that is too frequently overlooked. Where nearly vertical wave fronts exist, reflections, inductance, and minute amounts of distributed capacitance take on exaggerated importance compared with their effects under the more usual conditions. All results given by the crest meter under these conditions must be interpreted accordingly. Where vertical wave fronts are present this is a difficult task, but in the more usual case where the wave front has been rounded off the crest meter is still serviceable.

C. L. Fortescue: Referring to Mr. Frederick Terman's paper on Measurement of Transients, this question of the Measurement of Transients of transmission lines and in apparatus connected to transmission lines, is becoming of great importance. However, there are surges of several kinds; we may have surges of very high voltage, which last for a very short time, so short that they do not do any damage.

It takes more than the application of a high voltage to puncture insulation. Insulation requires time as well as voltage in order to be injured, so that what we really need in the measurement of these transients, is something which will weigh the effect of the surge or transient, so as to give some measure of its real destructiveness.

The mere recording of the maximum values does not appear to be sufficient and may be quite misleading. We ourselves in the Westinghouse Company are working on this problem of developing a device that will record transients, and we are at the same time considering some device that will also give a measure of the destructiveness of the transients.

I have had occasion to do some work on transients in connection with transformers, the switching transients that occur in the transformers. These transients occur across the terminals of transformers and across portions of the lining after the transformer has been removed from the circuit. They may reach four or five times the normal voltage across those portions of the transformer; but usually they are of such short time, and have such a small amount of energy, that they have little effect on the insulation. This is particularly true in connection with oil transformers.

As I said before, it requires more than a high voltage to injure insulation. It requires also an appreciable amount of energy, or what is the same thing, voltage, plus time.

Balance Methods in Alternating Current Measurement

BY PERRY A. BORDEN

Member A. I. E. E.
Hydro-Electric Power Commission Laboratories, Toronto, Ont.

INTRODUCTION

IT is the purpose of this paper to describe a system whereby many of the advantages of balance methods of measurement may be made applicable to the study of alternating-current quantities which do not lend themselves to easy measurement with ordinary indicating instruments. Convenience, rather than extreme precision is aimed at. These tests are carried out without the use of vibration galvanometers, synchronous contactors or the need of precise frequency control. The asynchronous detector, using the "heterodyne" principle at commercial frequencies is described. In current measurement use is made of the three-coil transformer or "test ring." There is illustrated the application of a simple method of plotting the vector positions of measured currents; and in conclusion there are shown a number of practical applications of null and semi-null methods of measurement. A bibliography dealing with kindred problems or cases where the methods here described might be applicable in whole or in part, is appended.

The advantages of opposition or balance methods of measurement, except where speed is the primary requisite, are too well known to require elaboration in this paper. They may be used, not only for measurements where extreme precision is required, but also in the determination of electrical quantities which are too minute to operate instruments of the direct-deflecting type, or which emanate from sources where conditions would be disturbed by the introduction of such instruments. Since alternating-current instruments are of inherently lower sensitivity than those for direct current, it follows that the need for opposition methods of test are more pressing here than where meters of high sensitivity are available.

In alternating-current work, the use of opposition methods has been seriously handicapped by two conditions which for direct current do not apply. These are, first, the difficulty of obtaining a suitable opposing current or electromotive force; and, secondly, that of detecting a condition of true balance between the opposing quantities. While these troubles have been fairly well overcome for tests where the most perfect conditions of wave form, frequency regulation and freedom from outside disturbances are available, the expense of the equipment, and the delicate conditions of operation seriously interfere with the use of these methods in ordinary commercial laboratories and testing shops. The value of opposition methods in alternating-current work is probably best exemplified in the Drysdale¹

potentiometer; but, as is well known by all who have studied this device, any of the interfering conditions mentioned above will seriously limit its usefulness.

The methods of test described below are not in any sense those of the extreme precision of the standardizing laboratory; but are intended to illustrate how, with comparatively simple and common instruments, and apparatus which can be built up by any good mechanic there may be made measurements on alternating-current quantities of small value or of poor regulation which will be far more satisfactory than those directly obtainable with indicating instruments.

Opposition methods of measurement may be classified under the two heads of "null" and "semi-null," or "balance" and "balance-deflection." *Null* methods are those in which the quantity to be measured is opposed by a similar quantity both adjustable and measurable, the difference reduced to zero, and the measurement performed upon the latter quantity. In *semi-null* measurements, the opposing quantity, while measurable, is not of necessity adjustable. The final measurement is performed upon that quantity which represents the difference between the other two. Referring to Fig. 1, if OA represents a vector quantity which it is desired to measure, and OB be a vector of adjustable and measurable magnitude and phase position, the null method of measurement would consist in reducing AB to zero and measuring OB . The semi-null method would call for a measurement of AB , which, combined with OB would make possible the derivation of the value and position of OA . Each of these classes of measurement has an important place in alternating-current work; and in some cases they may be combined in the one test. In this discussion they will, as far as possible, be studied separately, the null method receiving the first consideration.

FIG. 1

Null Methods

There are three requisites to the use of the null method in electrical measurement, first, the opposing quantity, against which is balanced the quantity under investigation; second, a means of detecting when a condition of balance exists; and, third, a means of measuring the opposing quantity as to magnitude, and possibly as to phase position. These three requisites are dealt with in order.

SOURCE OF OPPOSING CURRENT OR E. M. F.

In direct-current null method work, (probably best

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 14-17, 1923.

exemplified in the simple potentiometer), it is necessary only to oppose the current or voltage being measured by a similar quantity derived from a separate battery and adjust the magnitude of the latter quantity, until a balance is obtained. With alternating currents it is necessary to derive the opposing force from a source synchronous with the quantity under investigation, and to provide means whereby not only the magnitude but the phase position may be adjusted with accuracy. There are several ways in which this may be accomplished. It may be done by a combination of rheostats fed from a polyphase source or by a similar combination of tapped transformers, or by the use of inductances and capacities but these schemes are awkward and do not lend themselves to fine adjustment unless elaborate interconnections are used. Probably the best method lies in the use of a separate alternator driven synchronously with the supply and capable of having its field structure shifted about the armature. Such machines, however, are not very common, and unless one has the facilities of the electrical manufacturing plant at his dis-

FIG. 2

posal, are likely to be disproportionately expensive. The most workable method is in the use of the induction type of phase shifting transformer. This is similar in construction to the feeder voltage regulator, being built like an induction motor with a wound rotor, having its stator energized from a polyphase source to produce a rotating field. The secondary winding may be either single-phase or polyphase; and the rotor is adjustable to any desired position. Phase-shifting transformers manufactured especially for the purpose are available, and are made with a smooth core, practically eliminating wave distortion. The apparatus used by the writer, however, was constructed from a small three-phase motor, having the rotor bars removed and replaced by a well distributed single winding, and the rotor fitted with a worm wheel and graduated dial. While a slight wave distortion was visible when the primary and secondary voltages were opposed and an oscillogram made of the residual voltage, this was not found to affect results to any appreciable extent; and while the graduated dial was used merely as an indicator of the rotor position, its readings were usually found to be in remarkable agreement with phase

positions as determined by precise methods. By means of a small auto-transformer and a potentiometer arrangement of resistances supplied from the secondary of the phase shifter it was possible to obtain voltages and currents which could be adjusted to a very nice degree of precision. The general arrangement of the phase shifter is shown in the wiring diagrams illustrated in Figs. 4 and 5.

DETERMINATION OF BALANCE

Probably the greatest drawback in alternating-current methods of potentiometry, and null methods in general has been the determination of a condition of balance. For direct current there are available numerous galvanometers and detectors, the most popular doubtless being the D'Arsonval galvanometer. Failing this, it has been possible to use the telephone with some form of interrupter introduced into its circuit. On alternating current we have not the same flexibility of choice. High sensitivity instruments having permanent magnets are, of course, not directly applicable; and instruments of the moving iron or single-circuit electrodynamic type, operating on a law of squares, lose their sensitivity as the zero point of the scale is approached. The telephone may, of course, be used; but as it has a low sensitivity on commercial frequencies, it is almost as necessary to use an interrupter as on direct currents. To this difficulty is added the effect of harmonics; for, while the fundamental may be balanced out, the unbalanced harmonics, to which the telephone is much more sensitive than to the fundamental, have a very disturbing effect. A galvanometer of the permanent magnet type may be used, the balancing current being led to it through a synchronous contactor; and while in many tests this arrangement has proved most satisfactory, there remains the drawback that if a complete balance is desired, observations must be made with more than one position of the contacting points relative to the field of the driving motor. Similarly, a detector of the dynamometer type with a separately excited field may be used, the excitation being obtainable from two out-of-phase sources, synchronous with the supply. With either of these detectors it is possible to obtain a balance by alternately using the two brush positions, or field excitations, as the case may be; and balancing, first on one and then on the other, until no deflection is obtained with either, which, of course, is the condition of true balance. This method, while quite workable, has been found slow and cumbersome, as well as very confusing unless extreme care is exercised in the sequence of adjustments. There remains, of course, the vibration galvanometer, which is undoubtedly the most sensitive detector we have for this work. It requires, however, a closely regulated frequency, which is often not obtainable; and it must be carefully protected from outside mechanical vibrations. These features seriously limit its use except under the most exacting conditions.

As an outcome of these methods of detection, there has been developed by the writer a system whereby the deflection of balance is greatly facilitated; and this, to borrow the terminology of the radio engineer, may be termed the "heterodyne" method; and the detector the "heterogalvanometer" or "heterodynamometer," according to the equipment used. This consists, in brief, in replacing the synchronous contactor which would ordinarily be used with the D'Arsonval galvanometer by an asynchronous contactor, or the synchronous field of the electrodynamic instrument by a field derived from a source slightly differing in frequency from the supply. If a galvanometer is being used, the change to a "heterogalvanometer" is made by driving the contactor at an asynchronous velocity, when the galvanometer will oscillate with a periodicity corresponding to the difference between the frequency of the supply and that represented by the speed of the contactor. It is at once evident that this may be very simply accomplished by direct attachment of the contactor to the shaft of an induction motor driven from the supply, when the oscillations of the detector will represent the slip of the motor. In balancing, it then becomes only necessary to adjust until the oscillations of the detector cease, when it is known that the current flowing in its coil has a value of zero, and that consequently there is a true balance between the opposed quantities. If an electrodynamic instrument is to be used as a "heterodynamometer," the field is excited from a separate source, having a frequency differing slightly from that of the supply. If a separate motor generator is available this may be very conveniently done; and by slight adjustments of its frequency, an excellent control obtained of the period of swing of the detector. If an alternator is not at hand, a suitable off-frequency supply may be obtained by passing direct current through a "rectifying" commutator attached to the shaft of an induction motor. All these methods have been used by the writer with good success. Excellent results have been obtained by the heterogalvanometer method, using a Leeds and Northrup portable indicating galvanometer as a detector; while for the heterodynamometer method, use was made of a re-modelled Weston Model 18 voltmeter. In this instrument the fixed and movable circuits were separated and brought out to different sets of terminals, the windings being left unchanged, with the exception of an auxiliary field circuit of a comparatively few turns, used for "feeling out" conditions. The zero point was brought to the center of the scale, and a new calibration made, using a constant field and a varied current in the moving coil.

MEASURING AND LOCATING THE OPPOSING QUANTITY

When a condition of balance between the measured and opposing quantities has been obtained, there remains the problem of determining the magnitude, and possibly the phase position of the latter, from which to derive the former. If the quantity under measurement be a

current, and its value be beyond the range of ordinary indicating instruments, it is necessary to make use of a three-coil transformer, which is described under the head of "Measurement of Current." If a small voltage is being investigated, a potentiometer arrangement is made up, and a measurable voltage obtained. These quantities would then be determined as to magnitude with direct indicating instruments of any reliable type. As it is frequently desirable to find the vector position of the current or voltage, as well as its magnitude, there is described below a method developed by Mr. H. S. Baker, and capable of almost unlimited application.

Assuming a sinusoidal wave and a constant voltage, the indication of a wattmeter or of any instrument of the electrodynamic type is in proportion to the projection of the vector representing the current in one circuit upon that representing the field produced by the

FIG. 3—TRANSPARENT SCALE USED IN PLOTTING VECTORS

other; or, to be more lucid, though perhaps not so precise, the reading of a wattmeter represents the projection of the current upon the voltage. Conversely, the locus of the end of the current vector will be a perpendicular to the voltage vector drawn through a point on the latter representing, in its distance from the common origin, the indication of the instrument. Now, if an equal voltage of different phase position be applied to the instrument, the current remaining as before, the end of the current vector will lie also on a perpendicular drawn through the new voltage vector at a point representing the new indication. Since these results are obtained with the one current, it follows that the intersection of the perpendiculars locates the end of the current vector, thus definitely fixing the position of the current in relation to the two voltages. In a similar way any number of current vectors may be plotted by projecting them against the same reference voltages.

This method of plotting vectors is illustrated in Fig. 2. The vectors "*l*," (left), and "*r*," (right), are the two reference vectors, representing the field excitations which are used in the wattmeter or dynamometer. The indications of the instrument as read with a single current projected against first one and then the other of these are scaled off along the respective vectors. The position of the end of the current vector will then lie at the intersection of perpendiculars drawn through these points. Suppose the readings with the left and right hand vectors had been 59 and 68 respectively; the procedure would be as follows: On vector *l*, using any convenient scale, measure off a distance of 59 units, and erect a perpendicular. On vector *r*, using the same scale measure off 68, and erect a perpendicular. The intersection of these perpendiculars gives the point A, the end of the current vector. In a similar way any number of current vectors may be plotted by projecting them in a dynamometer, against the same reference vectors.

While the above is taken as referring to the location of current vectors, it will be seen that with two equal current vectors at a fixed angle it is equally easy to locate voltage vectors. The reference vectors may be at any convenient angle; but practical considerations would usually make this angle sixty degrees, as derived from two phases of a three-phase system. The plotting of vectors by this system is facilitated by the use of a transparent scale similar to that shown in Fig. 3.

Having described the three elements of the test—the source of opposing current, the balance detector, and the plotting of the vectors,—we may now proceed to the discussion of some applications of the methods in actual work.

MEASUREMENT OF CURRENT

The general diagram of connections for current measurement is shown in Fig. 4. When the current investigated is not of a magnitude conveniently measurable on the indicating instruments at hand, use is made of a three-coil transformer or "test ring." Great flexibility of design is here possible, almost any small transformer with three separate windings about its core being adaptable to the work. Excellent satisfaction has been obtained by the writer by making use of a "Baker test ring," designed for current transformer ratio and phase-angle measurements. This ring carries three windings, which may be referred to as "primary," "secondary," and "tertiary," though here these terms are not in strictly correct usage. As employed in these tests, the primary consists of two turns wound on the ring and carrying the opposition current derived from the phase-shifter. The secondary winding, set to 200 turns carries the current which was under measurement. The tertiary winding of some 7000 turns is led to the detector operating as a heterogalvanometer. The opposing current being adjusted until the detector indicates a condition of balance, it

follows that the flux in the magnetic circuit of the ring has a value of zero; and hence that the ampere-turns of the primary and secondary windings are equal and opposite. Under these conditions the transformer is operating at its true turn-ratio; so that the measured current will be a definite and known multiple of the opposing current, and in exact phase opposition. The opposing current then being measured as to magnitude and vector location, the same information is obtainable in regard to the measured current by applying the turn

FIG. 4—MEASURING SMALL CURRENT, USING "HETEROGALVANOMETER" DETECTOR

ratio of the transformer. With the set-up described above, the writer has been able to measure and definitely locate currents of the order of one tenth of a milli-ampere; and there does not appear to be any obstacle in the path of far greater refinement if found desirable. The same general scheme, with a reversal of ratio arrangement would be suitable for measurement of very large currents. In cases where the current is of a magnitude measurable by instruments at hand, the test ring may be omitted and a direct opposition con-

FIG. 5—MEASURING SMALL VOLTAGE, USING "HETERODYNAMOMETER" DETECTOR

nection used. A cut of the actual apparatus used is shown in Fig. 7.

MEASUREMENT OF VOLTAGE

The connections for voltage measurement are shown in Fig. 5. It will be seen that, with exception of the replacement of the test ring by a non-inductive tapped resistance of the potentiometer type, the arrangement is practically the same as that for the determination of current. If a non-inductive adjustable potentiometer

is at hand, it may be possible to apply the true potentiometer principle to the test; when the method closely approaches the system developed by Dr. Drysdale.²

MEASUREMENT OF POWER

The application of the null method to measurement of power suggests itself, and requires little explanation.

FIG. 6—SIMPLIFIED DIAGRAM SHOWING MEASUREMENT OF DIELECTRIC LOSS IN CABLE

In the measurement of small wattages or of power in circuits which would be disturbed by the introduction of instruments, it is seldom that both current and voltage would require a null method of measurement. Such being the case, the directly measurable quantity is led in the usual way to a suitable wattmeter, and the other quantity transferred by the null method to the

instrument; when the proper ratios being taken into consideration, the wattmeter will indicate the actual power in the circuit. Here, of course, if the power be at low power factor, as is frequently the case, careful allowance must be made for phase angle of the instru-

ment transformer (if any) used in the direct measurement. A system of connections for power measurement is shown in Fig. 6.

DETERMINATION OF INDUCTANCE AND CAPACITY

Inductance measurements may be made by plotting the voltage across the circuit investigated, and comparing it with the drop across a non-inductive resistance carrying the same current. This will give the phase angle, from which the inductance may readily be derived. In an exactly similar way capacity may be determined. If more convenient, the voltage may be taken as the fixed quantity, and measurement made upon the currents flowing through the circuits.

Semi-Null Methods

While semi-null methods of opposition are commonly used in alternating-current measurement, it is thought well to briefly recapitulate some of these applications, more with a view to collecting the matter under one head, than with any object of introducing new material.

FIG. 8—CONNECTIONS FOR CHECKING WATTMETER BY SEMI-NULL METHOD

A: Standard Instrument; B: Instrument being checked; C: Low reading instrument, indicating error.

TRANSFORMER RATIOS

A considerable number of methods of determining instrument transformer ratios by opposition methods are in vogue; and the principal differences among these lie in the way of dealing with the differential current or voltage representing the amount by which the transformer departs from its intended ratio. While it will at once be evident that the null methods described above may be applied in the study of these small vector differences, it is frequently possible to dispense with this refinement; and, by means of the system of reference vectors, directly examine the differential current or voltage, whence may be derived the constants of the transformer.

In testing current transformers with the "Baker test ring,"³ previously referred to, the primary and secondary currents of the transformer under test are made to

²See Bibliography.

³See Bibliography.

circulate in opposition about the ring, (the respective windings having first been set to the nominal ratio of the transformer) and the vector difference of the two sets of ampere-turns as derived from the tertiary winding examined against reference vectors in a dynamometer. By introducing known errors into the turn ratio of the ring, a number of vectors are obtained, from which a diagram may be constructed, giving graphically the constants of the transformer to a high degree of precision. A similar method may be applied to the testing of voltage transformers against a standard potentiometer; but the possible errors due to current flowing in the tap impose limitations which make desirable the use of a null method or the employment of a standard transformer.

INSTRUMENT CHECKS

A method has been published by the writer⁴ whereby increased precision in the comparison of indicating

FIG. 9—DETERMINING TRANSFORMER LOSSES BY SEMI-NULL METHOD

A: Two-element (polyphase) wattmeter; B: Low reading wattmeter, indicating losses.

instruments with standards is made possible by a semi-null method. This is particularly applicable to wattmeters, but with certain limitations to ammeters and voltmeters also. Here, an auxiliary current is passed through the circuit of one of the instruments under test, as shown in Fig. 8, both instruments thus being brought to an identical reading. This auxiliary current being then measured in an instrument of comparatively high sensitivity, the difference in accuracy of the two instruments under comparison is thus shown in a greatly magnified form.

EFFICIENCY MEASUREMENT

A semi-null method of efficiency measurement has been developed and used with considerable success on

See Bibliography.

pieces of apparatus wherein both the input and output are electrical quantities⁵. This can be applied in the case of transformers and some motor-generator sets. The system, as illustrated in Fig. 9, consists in passing the input and output in opposite senses through the circuits of a two-element wattmeter such as is commonly used for polyphase measurements, and adding an amount of power derived from a separate source to the output side of the instrument, to balance the two, and bring the wattmeter to zero indication. This comparatively small quantity may then be measured on a separate wattmeter of suitable range, giving a magnified indication of the losses in the apparatus tested.

CONCLUSIONS

The tests which have been described above cannot in any sense be said to exhaust the possibilities of opposition methods of measurement as applied in alternating-current work. The instances which have been cited are given as thoroughly practical examples, and as cases which are backed by the author's experience. It is felt that all who have studied this branch of electrical measurement or who are in their work confronted by problems of measurement which seem to surpass the capabilities of the instruments and equipment of the ordinary commercial laboratories will be able to find in this study many helpful suggestions. In the course of the paper, a number of references are made to the investigations and developments of Mr. H. S. Baker of the Ontario Power Company, whose earlier work along the lines here set out has been of inestimable assistance to the writer, and whose inspiration has been a continual incentive to carry the development of balance methods of testing to a further degree of perfection than has heretofore been published; and the writer takes this opportunity to pay a part at least of the debt of gratitude which he owes to Mr. Baker's infinite genius and kind cooperation in the working out of these methods of testing.

SUMMARY

(1) Owing to the comparatively low inherent sensitivity of alternating-current instruments, balance or opposition methods of measurement are more desirable and of wider application in alternating-current testing than in direct-current work.

(2) The application of balance methods to alternating-current tests is a greater problem than in direct-current work, because of the necessity of having to oppose the measured quantity in phase position as well as in magnitude; and because of the difficulty of precisely detecting when a condition of balance is obtained.

(3) A suitable source of current or voltage for opposition tests consists in the phase-shifting transformer, to which is added a potentiometer type of rheostat.

(4) A satisfactory detector is found in the D'Arsonval

5. See Bibliography.

galvanometer or the electro-dynamometer, so arranged that the indicator oscillates at an easily observable periodicity. A condition of balance exists when the oscillations have been reduced to zero.

(5) In current measurement, use is made of a transformer having three windings, the measured and opposing current flowing in two of these windings, and the difference, as derived from the third, reduced to a zero value, when the ratio between the active currents becomes the turn ratio of the transformer. With this arrangement it is equally easy to measure extremely small or extremely large currents.

(6) In voltage measurement a simple potentiometer arrangement of resistance is used, the ratio being set to a suitable value at the beginning of the test.

(7) The opposing current or voltage, after a balance has been obtained, may be measured by indicating instruments, and if desired, its vector position plotted, by means of a pair of readings obtained with an instrument of the wattmeter type against two "reference vectors."

(8) Null methods of test may be applied to measurement of quantities of current, voltage or power which are either too small, (and in some cases too large) for instruments of ordinary types, or are derived from sources wherein conditions are so unstable that they would be disturbed by the introduction of these instruments into the circuit.

(9) Semi-null methods, where a complete balance is not obtained, are applicable to transformer ratio measurements, instrument checks and, in some cases, to the measurement of efficiencies.

Discussion

C. L. Fortescue: This question of Null measurement is one that has been discussed in the Institute in the past quite a good deal. I think that Null methods of calibrating current transformers are in general use now. We ourselves have used a method of calibrating current transformers which was described by me in the Institute JOURNAL some time ago, in which variable mutual inductances were used. At that time we used d'Arsonval portable type galvanometer, and a synchronous contactor. This method was quite satisfactory so long as the contactor was properly maintained; but as we were using this apparatus right on our test floor, with green operators from time to time, who had to be trained to use the device, it was difficult to get them familiar enough with it to be able to tell when it was working properly, and the results were sometimes erratic.

We therefore changed over from the D'Arsonval instrument and synchronous contactor and used instead a dynamometer type instrument, which was excited from a synchronously driven motor-generator set through a phase-shifter. This could be adjusted to give maximum sensitivities for a change in e. m. f. in quadrature to the current or a change of e. m. f. in phase with the current. Thus we had two sensitive positions, and in adjusting our circuit, so as to get zero reading we alternated these two positions making the necessary adjustments until zero reading was obtained.

Now, this hetero-galvanometer or hetero-dynamometer scheme passes through both those positions during the cycle, and instead of getting steady measurement to be reduced to zero, we get slow cyclic measurement to be reduced to zero, so that it amounts to the same thing, but the method used by us is much quicker and simpler to adjust.

However, Mr. Chubb and I made use of this method of a commutator driven at slightly below synchronous speed, a number of years ago, in connection with the calibration of the sphere-gap voltmeter and we found it quite effective. Of course, we were not using it with a Null method, but for direct measurement of crest voltage.

We are using the Null method device which I have described for calibrating current transformers right in our transformer test floor and we have very little trouble now. We are able to detect differences down to a small fraction of a micro-ampere.

I. M. Stein: Mr. Borden has stated that a-c. instruments are of *inherently* lower sensitivity than those for direct current. I believe that the lower sensitivity to which he refers is not inherent but is brought about by the conditions imposed by the use of the instruments. If the conditions are such that an iron-core-electrodynamometer can be used you can obtain as good sensitivity with an a-c. instrument as you can with the best d-c. instruments.

On page 36, Mr. Borden indicates that high sensitivity instruments having permanent magnets are not directly applicable. I do not believe that he intends to exclude the vibration galvanometer because this instrument is mentioned later on but from the statements made one would be led to believe that vibration galvanometers were not made with permanent magnets. Where the vibration galvanometer is mentioned, the paper states that the vibration galvanometer "is undoubtedly the most sensitive detector" for such work. This is not true because the iron-core electro-dynamometer is capable of much greater sensitivity. However, the vibration galvanometer is an excellent instrument for such work and is of particular value in exploring the circuits for stray field effects before starting measurements. In d-c. measurements it is usually satisfactory to shield the measuring instrument from stray fields but in a-c. measurements it is necessary to shield the whole circuit. The fact that the vibration galvanometer responds to all currents of the fundamental frequency regardless of phase relations makes it an ideal instrument for preliminary stray field explorations.

I do not agree with Mr. Borden that the use of the separately excited dynamometer is "slow and cumbersome." That is a matter which depends very largely upon the design of the instrument and its accessories; when properly designed and applied. The use of the separately excited dynamometer is very rapid and convenient.

Referring to the asynchronous commutator and galvanometer to which Mr. Borden has given some new names, I do not believe that the device can be called new. An instrument using this principle and called the "Ondograph" has been in use for more than 10 years. A similar arrangement for measuring a-c. wave form was described in the Institute TRANSACTIONS several years ago. About 3 years ago Mr. Doyle of the Electrical Testing Laboratories described to me a device which he had built and tried out in connection with instrument transformer testing. This device was identical with the one which Mr. Borden describes.

Concerning a-c. opposition methods Mr. Borden has stated that such methods are best exemplified in the Drysdale potentiometer and goes on to say that this instrument is seriously limited in its usefulness. I am afraid that nearly all a-c. measuring instruments are seriously limited but that should not be discouraging. I believe that opposition methods in a-c. work are best exemplified by some of the very useful and convenient methods which have been developed for a specific purpose. I refer to the opposition methods which have been developed for testing instrument transformers. I believe that a mistake is often made in designing an instrument to make too many measurements; accuracy, rapidity and convenience are thereby sacrificed. Concerning the use of the word "Null" I cannot agree with the definition which Mr. Borden has given. A "Null method" is defined in Funk and Wagnall Dictionary as follows:

Null Method: "A method of measurement in which the thing to be observed is not the degree or extent of a thing but merely whether the thing occurs at all, as when the equality of an electrical resistance, with another against which it is balanced, is indicated by the absence of deflection of a galvanometer needle."

I should not consider this source of information a final authority on such matters except that the definition expresses very clearly the generally accepted idea.

There is one point in Mr. Borden's paper which is not brought out as clearly as it deserves to be. This point is in connection with the arrangement shown in Fig. 4. While I do not agree that this arrangement should be called a null method, I believe that the circuit has considerable merit, at least for certain kinds of measurements.

If my interpretation of Fig. 4 is correct, the outstanding advantage of this circuit is that the current in which you are interested can be measured without materially impeding its flow. When the adjustments are made so that a balance ob-

tains, it would appear that the only impedance to the flow of the current is the resistance of the secondary winding.

In measuring small alternating currents, the resistance of this winding would probably be very much lower than the impedance of any instrument winding which you would have to insert in order to obtain the desired sensitivity.

If the circuits in which the current is to be measured were located some distance from where the measurements are to be made, then by placing the ring at the remote point, the impedance of the lead wires between the two locations would be eliminated. Of course, it would be necessary to run four wires instead of two, but in many cases there would be no objection to this, and the elimination of the impedance of the lead wires would be a distinct gain.

H. B. Brooks: Mr. Borden's paper is one of a number of evidences of the great potential usefulness of the potentiometer or balance principle, and it reminds us of the fact, often overlooked, that deflection instruments disturb conditions in the circuit to which they are applied.

In using the two-element wattmeter as suggested by Mr. Borden, it should be kept in mind that the two elements are in general not exactly balanced and that the amount and sign of the unbalance differ from point to point over the scale. For careful work the amount and direction of unbalance at the zero point should be determined, and a suitable correction applied.

Chester L. Dawes: Mr. Borden mentions the Drysdale potentiometer as illustrative of one of the null methods. At Harvard University, we require of each senior electrical engineering student four or five experiments involving the use of this apparatus, and we find it highly satisfactory. It requires perhaps two experiments to give the students skill and confidence in the manipulation of the apparatus. Two, and sometimes three experiments are given in which the students measure the current and voltage relations along artificial lines. As a rule, we use a Campbell bifilar vibration galvanometer as a detector, since it is not affected by stray fields as is the Tinsley magnetic-vane type. I have found that after some practise in the manipulation of the apparatus, balances can be rapidly and accurately made, provided the frequency and voltage are maintained constant. Our power is supplied by a 12 kv-a. alternator, driven by a 20 h. p. d-c. motor. Since we are able to control the field current of either machine from any laboratory, we have little difficulty with variations of frequency or voltage.

I have also used this potentiometer in the investigation of losses occurring in the leads, bus-bars, and adjacent iron supports of large brass furnaces. The potentiometer was set up in a small laboratory adjacent to the furnace room in a large manufacturing establishment. The commercial, 60-cycle power system was used for supply. Currents as high as 5000 amperes were involved, and e. m. fs. of the order of a few millivolts were measured. Balances could usually be obtained rapidly and accurately, even under these commercial conditions. Twice during those times when the main power plant was not in operation, and a small, lightly-loaded, turbo-alternator was carrying the load, some difficulty was experienced in obtaining balances, owing to the slight hunting of the turbine. The fact that the governor was not holding the turbine speed absolutely constant was not appreciated at the power plant until this time.

From my own personal experience, I feel that this type of potentiometer is very useful, and in many cases may be adapted to commercial measurements. Personally, I prefer the simple, vibrating galvanometer to the "heterogalvanometer" method described by Mr. Borden, since the asynchronous contactor adds considerably to the complication of the apparatus.

There is another type of a-c. potentiometer, called the rect-

angular¹ or two-dimensional potentiometer, which perhaps is not so well known as the Drysdale, because it has not been generally described in textbooks and engineering literature. A simple diagram is shown in Fig. 1.

R is a non-inductive potentiometer wire, which may be subdivided by any of the various methods employed with d-c. potentiometers. The working current i is maintained at its correct value by a rheostat r , this current being measured by some type of a-c. milliammeter A . This milliammeter is preferably of the dynamometer type, since this type may be calibrated with a standard cell, using reversed d-c. readings. We have also found a vacuum thermocouple, used in conjunction with a d-c. milliammeter, very satisfactory. A hot-wire milliammeter is also satisfactory, if sufficient sensitivity is obtainable. The primary P of a mutual inductance M is connected in series with R . D is a detector. The component of the unknown e. m. f., which is in phase with i , is balanced along the resistance R . The component which is in quadrature with i is balanced by an e. m. f. $M \omega i$ supplied by the secondary of the mutual inductance M ($\omega = 2 \pi f$), where f is the frequency in cycles per second. The unknown e. m. f. is therefore determined as two quadrature components, one along the axis of reals and the other along the axis of imaginaries. By using a reversing switch and positive and negative values of M , e. m. fs. in any of the four quadrants may be measured. This type of apparatus is simple, does not require a phase-shifter, and may be made of apparatus usually to be found in the measuring-laboratory equipment.

I have found many instances where mutual inductances may be used for making e. m. f. measurements by null methods.

FIG. 1

I have also used the separately-excited dynamometer as a detector. Instead of obtaining two balances, one with the dynamometer across one phase of a polyphase system, and then across another phase, I have excited the dynamometer from the secondary of a small phase-shifter. In using a separately-excited dynamometer, one or two precautions are necessary. If the moving coil has a metal bobbin, and its plane does not coincide with the direction of the magnetic field, the induced currents in the metal will cause deflection, even though the moving coil is open-circuited. Even with a non-conducting bobbin, this same effect may occur, but to a lesser degree, due to the fact that a current flows in the moving coil windings, because of the capacitance between turns. Therefore, care must be taken when using this type of detector.

I have also used a Drysdale² polyphase phase-shifter to supply the current to the Drysdale potentiometer. This phase-shifter does not differ in principle from that described by Mr. Borden. It is more satisfactory than the phase-shifter supplied with the potentiometer, since the rather tedious task of splitting the phase accurately is eliminated, and also it is independent of the frequency.

"A Rectangular-Component, Two-Dimensional, Alternating-Current Potentiometer," Kennelly & Velandar, *JOURNAL. Franklin Institute*, July, 1910.

2. "Electrical Measurements," F. A. Laws, page 502.

I have used rotating synchronous contactors of the commutating type, and in one or two cases have experienced difficulty due to frictional electricity being generated. For this reason, I have found that contacts which are opened and closed synchronously by some type of cam are more satisfactory.

I have not as yet had an opportunity to test Mr. Borden's heterodyne methods, and therefore cannot compare them with the methods which I have just described. Undoubtedly when there are slight but continuing fluctuations of voltage and frequency, more rapid balances can be obtained by the heterodyne method.

E. D. Doyle: Referring to Mr. Borden's paper (Fig. 8), it would appear to me that this is by no means a null or even a semi-null method. Every instrument there shows a deflection. With regard to the accuracy with which the checking can be done, one has the observational errors in both meters, *A* and *B*, and the only purpose that meter *C* can serve, is to read the difference between *A* and *B* when they are brought to a common indication. Of course, a meter can be held on a point with much greater accuracy than an observation can be made in between the cardinal points.

Referring to Fig. 9, the same observational error comes in as in Fig. 8. However, if the polyphase meter *A* were provided with a very weak suspension, that is, weak compared to the torques of the two elements, you may obtain very great sensitivity. We have applied this particular principle to a double dynamometer of the reflecting type, for comparing a-c. voltages with each other. We have an instrument which we built ourselves, and which enables us to compare a-c. voltages with an error of less than two-hundredths per cent. This is done with a meter which is only consuming about one-fifth of a watt. This particular type of double dynamometer is also available for making comparisons between alternating and direct currents, and may also be used for a number of other purposes, such as measuring an impedance in terms of a pure resistance, by connecting one element first across the resistance and then across the impedance.

Now with regard to detectors, we have had very satisfactory results from a synchronous rectifier and d-c. galvanometer. The rectifier we are now using has brass segments and butt copper brushes. When it is lubricated rather freely with ordinary machine oil we have no trouble at all from thermal e. m. fs., or bad contacts. We have also provided two sets of d-c. brushes, and a double throw switch, we can quickly throw from a position where we are sensitive in-phase voltages, to the reactive position and vice versa thereby making it much more convenient from the operating standpoint.

One other point which I would like to bring up in connection with the various methods of detection is the influence of harmonics in the wave on the particular apparatus. Of course, the vibration galvanometer is sensitive only to the fundamental frequency. The rectifier has a greater sensitivity for fundamental frequency, but any harmonics in the wave, will be detected to a greater or less extent, depending on the phase of rectification, and also on the order of the harmonic.

At a maximum the third harmonic will influence the galvanometer to one-third of its value; because in rectifying two of the loops will balance out, leaving only the third. In a similar way, the fifth harmonic will appear only to one-fifth of its value and so on. The double dynamometer, which has its two elements entirely separate from each other is affected only by the effective value of the wave irrespective of any harmonics which may be present.

P. A. Borden: Both Mr. Fortescue and Mr. Stein have compared the use of the synchronous with the asynchronous dynamometer, the latter gentleman being inclined to differ from my statement that the synchronous use of the instrument was "slow and cumbersome," as compared with the other. I have made many tests using the electro-dynamometer in a-c. work, both the indicating type, having about the sensitivity of an

ordinary wattmeter, and the reflecting type with a sensitivity comparable to that of a d'Arsonval galvanometer. In these tests I have found. I think I may safely say, without exception that the slow swing introduced by asynchronous excitation is much easier to reduce to zero than the two separate deflections necessary where excitation is derived from the same source as the test. This, of course, may lie partly in the accessory equipment used; and I may here say that practically all the apparatus employed in the work described in my paper is that intended for general use in a laboratory called upon to perform an immense variety rather than a great volume of tests, so that the primary object in the equipment is flexibility rather than specialized fitness for one type of test.

I am pleased to learn that use has been made of the asynchronous commutator in conjunction with a galvanometer. Upon trying this scheme, I was surprised that anything of such evident usefulness had not previously been employed; but being unable to find any published record of its use, by Mr. Fortescue or others, I was forced to refer to my own development of the idea.

Mr. Stein has taken issue with my statement that a-c. instruments are of *inherently* lower sensitivity than direct, and states that if you can use iron in an a-c. instrument you can get the same degree of sensitivity as in a direct. You can, *if you can use iron*; but conditions are unfortunately such that the use of iron is generally out of the question. Again, on reading the context, as it appears in the first paragraph of my paper, I think it will be quite evident that I was here referring to indicating instruments rather than to detectors as used in balance work; and it is a well known fact that even the best makers have not attempted to market a-c. instruments which for smallness of energy consumption could compare with instruments of the permanent-magnet moving-coil type. In the use of an instrument of the electrodynamic type, incorporating iron in its magnetic circuit, my experience is confined to a certain type of a-c. galvanometer, in which I found that before the damping resistance could be reduced to a value to cut out swinging on 25-cycle work, the circulating currents in this circuit, due to e. m. fs. set up in the moving coil completely obliterated the quantities under investigation. In my opinion, it would have been necessary in this case to fit the instrument with a torsion head and make all observations with the moving coil in the position of zero mutual induction with the field.

I think I may be pardoned for having overlooked the Hospitalier Ondograph as an instrument making use of the asynchronous commutator, in view of the fact that the use of that device as a wave tracer is so radically different from my application of the principle as a voltage detector that I had neglected to associate the two ideas. As to the use of the word "Null" in my work, I am quite ready to yield the point to Mr. Stein; and if my usage is not in strict accord with the dictionary definition of the word, admit the fact that I sought no higher authority than the generally accepted technical works and writers. As to whether in the particular instance to which Mr. Stein refers, I have properly classified the test under the heading of "Null," I leave to those interested, to decide. And at the same time I thank Mr. Stein for pointing out the wide uses to which may be put the circuit shown in Fig. 4.

I wish to thank Mr. Brooks for calling attention to the fact that the elements of a polyphase wattmeter may not be in exact balance, at zero or at other points of the scale; and while this was recognized by the writer, it is well to repeat that in tests of this class it is assumed that a high grade instrument is used, in which this unbalance is very small. At the same time; as the deflection of the wattmeter is by the method used reduced to zero, it is usually sufficient that the strengths of the respective elements be equal only at the zero point.

Mr. Doyle has called attention to the possibility of observational errors in the additional meter used in the calibration

described in Fig. 8. True, the error of the instrument *C*, as well as that of *A* comes in, but in a negligible degree. In the first place, *A*, the standard is read when indicating on a cardinal point *t*, which is much more definite than the interpolation which would ordinarily be necessary. At the same time, this would usually be a point whereon the accuracy of the standard was determined in comparison with a primary standard. In the second place any error in the calibration of *C*, appearing as an error in the error, would be of the second order of magnitude, and hence usually negligible. The possibility of observational errors, too, is much reduced; for once a setting has been obtained, it may be maintained indefinitely until the tester is assured that the principal meters are in agreement on the point at which the observation is being made, after which he may read the error, as indicated on *C*, at his leisure. What I have said in regard to observational errors in this test applies equally to Mr. Doyle's comment upon similar errors in the transformer test in Fig. 9,

with the additional feature that the wattmeter when finally balanced, is read only upon the zero point of the scale. A two-element meter with a weak spring would, without doubt, greatly increase the sensitivity of this test; but I have found the ordinary type of polyphase instrument, when used on the zero-deflection principle, to have sufficient sensitivity to prove itself of great value in this work.

In demonstrating this method of efficiency determination, I have often made use of a small motor-generator set, driven from a d-c. supply, and giving a single phase output. Such a set has, of course, comparatively large losses; and when the output and input are opposed in a two-element wattmeter, the convenience of the method becomes very evident. This method is particularly useful in determining the efficiency of single-phase rectifiers, and does away with much controversy as to the type of instruments used in the measurement of the rectified output.

General Considerations in Grounding the Neutral of Power Systems

BY H. H. DEWEY

Associate, A. I. E. E.

Asst. Engineer, Lighting Dept. General Electric Co.

Review of the Subject.—In the early days of power transmission, there was no consistent practise in respect to operating with neutral isolated or with neutral grounded. The rapid growth of transmission systems with their extensive networks soon began to show disastrous results from arcing grounds on isolated neutral systems and now most power transmission networks have their neutrals grounded in some manner.

The discussion of general considerations of neutral grounding is divided into two parts, that of overhead line systems and underground cable systems. He brings out the fact that while most overhead systems are grounded there is some difference in practise as to the extent to which they are grounded, that is as to whether they are grounded solidly or through resistance. Prevailing practise tends toward little or no resistance.

Attention is called to different possible methods of grounding a system and shows by diagrams the flow of short-circuit current with the different methods.

Underground cable systems are consistently operated with neutral grounded but general practise tends toward the use of resistance in neutral. General considerations as to protection from the

voltage strains due to arcing grounds on cable systems are similar to overhead line systems and the author analyzes briefly the character of cable breakdowns and general effect of such breakdowns with a view to determining the importance of the extent to which a cable system should be grounded. The conclusion in regard to cable systems indicates about the same limitations as those found for overhead systems and no very good reasons are found for a distinctive difference in practise.

The paper considers the use of grounding resistors of different types and gives some cast figures to show the effect of time and current in the design of metallic resistors.

The general conclusion arrived at is that, on either overhead or underground transmission systems, high-voltage strains are more to be feared than high-current strains and that resistance to limit ground current, if used at all, should be of very low value.

Cable Systems.	(2754 w.)
Conclusions.	(504 w.)

THE question of grounded neutral has been under discussion for many years and many papers have been written covering various phases of the subject from time to time, each with the purpose in view of presenting data tending to show the logic of the author's conclusions on the particular phase of the subject which has interested him. The general practise of the country has undergone certain changes during the past ten or fifteen years in the methods and extent in which systems have been grounded. These changes of practise have been brought about partly from the influence of individual writers' ideas as presented in the various papers mentioned and partly

by an actual change in the problem due to the rapid growth of our transmission systems during that period.

In the early days of power transmission, there was little to base one's judgment upon in determining the advantages or otherwise, of operating the system with the neutral grounded. Such experiences as had been obtained by the pioneers of transmission were complicated by conflicting evidence due largely to the fact that where trouble had occurred, it was often accompanied by the presence of many uncertain factors, and no direct comparison could be made between the isolated neutral and grounded neutral arrangement.

From the beginning of power transmission in 1888 or 1890 to 1910 or 1912, it is safe to state that there was

no general practise as regards the question of operating transmission systems either with grounded neutral or with the neutral isolated. During that period, transmission voltages increased at a very rapid rate, the length of individual lines for straight-a-way transmission greatly increased, and the number and length of interconnected lines forming networks handling thousands of kilowatts of power where hundreds had been handled before, presented an entirely new phase of the question.

A glance at the transmission problem of today seems to divide the question into two natural classes, that of overhead lines which have grown in extent and voltage to cover very wide areas handling large blocks of power, and that of underground transmission systems which cover smaller areas but with a much higher density of power per square mile and much lower transmission voltage.

The overhead systems generally speaking, vary in voltage from 13,200 volts to 220,000 volts and involve an aggregate of some 50,000 miles of line. There are several systems having a metallic connection of circuits extending well above 3000 miles at voltages around 44,000 volts and several systems having 1200 or 1500 miles of line at voltages of 110,000 volts or above.

The underground cable systems have an aggregate cable length of perhaps 10,000 miles and handle close to the same amount of power that the overhead lines do. An adequate discussion of grounded neutral versus isolated neutral, requires a careful consideration of the operating characteristics of the two types of systems and an analysis of the results of practical operating conditions from the early days of transmission to the present time.

OVERHEAD TRANSMISSION SYSTEMS

It probably can be truthfully said that in the early stages of transmission practise where the extent of the systems was small and the voltage low, there was no decided difference in the results of operating either with neutral grounded or ungrounded. As they grew in extent, voltage surges began to make themselves felt over wide areas, resulting in breakdown of insulation at various points. In seeking a remedy, many engineers grounded the neutral of their generators or transformers.

So many systems were installed simultaneously and at ever increasing voltage that there was not time to make an analysis of the advantages of either plan and such practise as was shown in the development of our American systems was the result of individual engineer's ideas and experiences during a period when development was too rapid to compare notes thoroughly and to build up a practise based upon weighted judgment and experience.

It has been the natural result then, that during the years from about 1904 to 1912 or 1914, many systems were put into service, some arranged for isolated neutral

and some for grounded neutral operation as well as others for what might be called a compromise between the two, that is, neutral grounded through extremely high resistance. During this period, then, it might be said that there were two schools of engineers making an impress on the practise of the country. Neither had very much past experience on which to base its judgment and their conclusions were drawn largely from theoretical considerations.

In the early days of high-voltage overhead line transmission development, certain principles of design and factors of safety of insulation were followed which results seemed later to conclude to be inadequate. Line insulators in particular showed too small a factor of safety and too short a life under operating conditions. The overhead transmission systems during the period mentioned have passed through many vicissitudes and few of the line insulators in use as far back as 1904 are still in service. We have gone to higher insulation and have vastly improved the design of porcelain insulators to make them stand up under operating conditions.

In 1912 or 1914 there were thousands of miles of overhead lines in operation on systems using isolated neutral and grounded neutral as well as some systems with the neutral grounded through high resistance. Sufficient experience had been obtained to enable engineers contemplating the design of new systems to take stock of past experience and the result of this stock taking seemed to indicate that the grounded neutral systems had certain advantages in most cases over the isolated neutral system. The evidence was not conclusive at that time and perhaps is not conclusive today, but there are certain fundamental principles that seem to be reasonably definite and most of them tend to show important advantages in favor of the grounded neutral systems.

The arguments in favor of the isolated neutral system, especially with delta connection, were that a single broken insulator would not cause a short circuit and consequent loss of service over an individual line and that the breakdown of a single transformer did not completely interrupt the service of an entire bank, as it was possible to operate with one line grounded or with two transformers out of three connected in open delta and maintain at least partial service. There was a third theoretical consideration that with delta-connected transformers, any disturbance coming in over one conductor, such as lightning or a steep wave front surge, would have its energy expended over two transformers and be less likely to cause serious damage. In the early days of transmission when the mileage and voltage were low, many systems operated for hours at a time and in some cases days, with one phase grounded and there was considerable use made of open delta connection of transformers on such systems.

It was argued that line insulators were designed to have the necessary factor of safety with full potential

to ground and that while the grounding of one phase increased the strain on a given insulator to 73 per cent above normal, it should entail no hardship as the insulator was designed for continuous operation on this basis. Practise, however, showed that most grounds of this nature were not solid grounds but were accompanied by severe arcing which produced oscillations tending to build up high-frequency and high-voltage disturbances which placed the whole system under severe strain and often resulted in breakdown of apparatus at different points on the system.

As the systems grew in extent and increased in voltage, the severity of the disturbances due to these arcing grounds, became a very serious menace to service, not only from the fact that breakdowns often occurred at widely separated points on a network as a result of an arcing ground at a given point, but these disturbances resulted in the breakdown of apparatus such as bushings, transformers, lightning arresters, etc.

As the amount of power transmitted grew, the importance of isolating cases of trouble to the section of line actually in trouble, became apparent. The great exposure to lightning, varying weather conditions, etc. of these extensive systems considerably increased the actual number of unavoidable breakdowns in spite of the greatest vigilance and the question of continuity of service became more and more important as the territory served, increased, and much energy was brought to bear on the study of protection for these systems.

Up to this time, the relay situation was not all that could be hoped for but improvements were going on constantly and there was every hope that if the distribution of current during breakdowns could be predetermined, satisfactory relays for selection of trouble, would be available.

An analysis of the character of breakdowns with this in view, gave some pretty definite indications that on isolated systems the problem was an extremely complicated one. Nearly all transmission line breakdowns occur initially as the failure of some weak insulator from lightning or other cause. The current flowing in the arc caused by this breakdown, is the charging current to ground of the other two conductors of the entire interconnected system. This current may be considerable, depending upon the amount of interconnected line, but is almost entirely wattless and shows up in such an uncertain manner as to be useless for selective relaying. During the time that this arc is playing over the weak insulator, the other two phases of the whole network are subjected to the strains due to this arcing ground until a second breakdown occurs, producing a short circuit from phase to phase and causing sufficient power current to flow to trip the relays.

It is evident that the location of the second breakdown will be uncertain and one that should not have occurred if the line in trouble could have been tripped

out by the relay before the arcing ground surge had time to spread the trouble. This second breakdown often occurs on an entirely different line, perhaps miles from the origin of the trouble and it is entirely within the range of experience to have several secondary breakdowns on different lines or different parts of the same line following an arcing ground at a given point. Such occurrences make selective relaying out of the question and a general shut-down of the system may well occur under such conditions.

The frequent occurrence of arcing ground troubles on isolated neutral systems led to the development of the so-called arcing ground suppressor which was brought out and advocated by Mr. Creighton and also by Mr. Nicholson, with the hope that a dead ground immediately placed on the phase in trouble would eliminate the destructive effects of the arcing ground and make it unnecessary to use relays to take the line out of service until inspection and necessary repairs could be made. The arcing ground suppressor however, was an expensive device and only a few were installed.

Another remedy for the elimination of a multiplicity of breakdowns was to ground the neutral of the circuit and thus make all initial breakdowns short circuits, which positively defined the flow of current and made possible the selective action of relays. As most systems feed their important stations by more than one circuit the loss of a line due to trouble is not prohibitive and the system of protection that has grown up on high-voltage networks has been to ground the neutral either solidly or through resistance and to make the maximum use of selective relays to cut off the section of line in trouble in the shortest possible time.

The good results obtained from grounding high-voltage networks and increasing the efficiency of protective relays has been such that the practise has extended to practically all overhead line work and the great majority of transmission line networks at all voltages from 22,000 to 220,000 volts are laid out with some plan of grounding the neutral. The usual practise is to establish a neutral by grounding the transformers at the source of power, that is, the generating station or generating stations as the case may be, employing delta-Y, step-up transformers at these stations. A definite flow of short-circuit current away from the generating stations is thus established and on straight-away transmission lines, particularly, leaves it optional as to the type of transformer connections that may be used at the step-down substations. Grounding at the generating stations and not the substations allows the use of delta-Y, step-down transformers at the substation, thus establishing the neutral point at the source of power for the secondary network emanating from these substations. This general practise may be followed on to the ultimate distribution system in several steps if desirable, each network in itself having its neutral grounded at the source of power.

There has been some difference in opinion as to the desirability of several neutral grounds on an overhead network at distant points, on account of the possibility of interchange current between neutrals which may affect telephone communication. There are, however, in operation, many extensive transmission systems with neutrals grounded at generating stations as well as at many substations with little, if any, telephone interference. The normal interchange of current between neutrals is usually so small as to be negligible and there have been in fact, only a few isolated cases where telephone interference due to circulating current in neutrals, has manifested itself. The conclusion from operating experience to date, indicates that no serious telephone interference under normal operating conditions need be anticipated even though the neutral is grounded at many points.

For the effective application of selective relays on a complicated network, a calculation of the short-circuit current with its distribution as to amount, direction and source, is of great value. Such calculations are comparatively simple with only one neutral grounded but where several are involved, each contributes to the ground current modifying the amount and direction, depending upon the location of these ground points. It is sometimes very difficult to predetermine this ground current with sufficient definiteness as to allow accurate selection and adjustment of relays so that in studying the question of grounding the neutral of a system, it is well to have this point in mind and to attempt a determination in advance as to the complications that may arise from the addition of neutral grounding points.

There is a number of possible combinations both in the connections and kind of transformers that may be used for grounding a system, and the different possible locations of ground points and an analysis of some of these combinations may be of interest.

The simplest arrangement is as shown in Fig. 1, with one generating station transmitting power over a single three-phase line to a substation. In such a case, delta-Y transformers would be used at the generating station with the neutral grounded at this point. The substation transformers may be connected in any manner, if there is no generating equipment at this point, without affecting the distribution of current. In such an arrangement with the ground at *G*, the flow of current will be in one conductor only, direct to the ground point and back to the neutral, appearing in one phase only in the transformer and two phases only in the generator. The calculation of this current is simply taking into account the reactance of the generator, transformer and line to the ground point.

Fig. 2, shows a similar arrangement of transmission line but with the substation transformers connected Y-delta with the neutral grounded at the substation only. The flow of current in this case is quite different from that in Fig. 1, and will be as indicated by the

arrows on Fig. 2. It will be noted that the current in all three legs of the substation transformer *Y* are equal and so far as the generating station is concerned, there are also heavy currents in all three phases; the current in the grounded phase, however, being double that in the other two phases. The reason for the equal distribution of current in all three legs of the step-down transformer will be apparent, in that, if there is current in the primary of the transformer of the grounded phase it must appear in the secondary and if it appears in the secondary, it must flow, and the only path is around the delta. This puts the same current in the other two legs which must again reappear in the pri-

FIG. 1—TRANSMISSION SYSTEM WITH NEUTRAL OF GENERATING STATION TRANSFORMER GROUNDED

Line ground at point "*G*". Arrows indicate flow of current

mary giving balanced current in the substation transformer which acts as a grounding transformer for the system.

Fig. 3, shows a case similar to Figs. 1 and 2 with the exception that both the generating station transformer and the substation transformers have their neutrals grounded. In this case the distribution of current will be similar to a combination of Figs. 1 and 2, current flowing as in Fig. 1, directly to the ground *G* from the generating station and appearing on one phase of the transformers and two phases of the generators. There will also be a current back from the substation neutral to the ground *G*, which current will appear in all

FIG. 2—SAME SYSTEM AS SHOWN IN FIG. 1, EXCEPT SUBSTATION TRANSFORMER NEUTRAL GROUNDED

three phases of the substation transformers. The flow of current to the ground from the generating station direct and the generating station by way of the substation, will depend upon the relative impedance of the various circuits and its calculation is somewhat complicated. For a comprehensive analysis of the calculation of single-phase, short-circuit currents on complicated networks, see article by W. W. Lewis, entitled, "Short-Circuit Currents on Grounded Neutral Systems" in the *General Electric Review* for June 1917.

Fig. 4, shows a similar arrangement of circuits but with two substations, each having Y-delta, step-down transformers with their neutrals grounded as well as

the neutral grounded at the generating station. The distribution of current on this system will be similar to that shown in Fig. 3, except that still greater complication due to the division of current among all three neutrals, will follow, the substation transformers having equal current in all three legs but the grounded phase in the generating station carrying the heaviest current. This again will divide up with relation to the impedance of the various circuits.

Fig. 5, shows an arrangement with two generating stations each having the neutral grounded, which introduces a combination of Figs. 1 and 3. The generating station "A" will feed direct to the short circuit. The generating station "B" will feed direct to the short circuit. Generating station "A" has a tendency to feed over the other two lines to the transformers in generating station "B" which will act similarly to the substation transformers in Fig. 3. Generating station "B" has a tendency to feed to the transformers in Station "A" and back to the short circuit in a similar manner. The distribution of current under such circumstances is problematical, depending upon the location of the short circuit with respect to the two stations assuming they are of the same size. If these stations are of different

delta which allows circulation of currents. It, however, is a rather inefficient grounding transformer as its reactance with one phase grounded is of the order of 50 per cent. That is, it will allow only about two times full-load current of the transformer to flow.

Another form of transformer that may be used to establish a neutral and allow heavy currents to flow in case of a fault to ground, is the so-called zig-zag or interconnected Y transformer which has no secondary winding as such. The winding on each core leg consists of two equal parts. The upper part of one leg is connected to the lower part of the adjacent; the three

FIG. 4—TRANSMISSION SYSTEM WITH GENERATING STATION AND TWO SUBSTATIONS
Transformer neutrals at all stations grounded

phases thus formed, being connected in Y and the neutral grounded. When a ground occurs on the line, this transformer acts similarly to a Y-delta grounding transformer as indicated in Fig. 2, equal currents appearing in all three phases. One-half the winding on each leg acts as a primary and the other half as a secondary winding, the currents in each half being equal and opposite in direction. Such a transformer is equal in efficiency as a grounding transformer, to a Y-delta connected transformer and generally speaking, will cost slightly less to build. Transformers of this type have been used to ground the neutral of systems

FIG. 3—SAME SYSTEM AS SHOWN IN FIG. 1

Neutrals of transformers at both generating station and substation grounded.

size, the relative impedances of the various paths to the short circuit will influence the division of current. The above examples will serve to call attention to the possible complication in relay equipment that may be encountered in systems grounded promiscuously. There are many other possible combinations that might be mentioned but they are nearly always only variations of the cases cited above.

It will be noted that in the suggestions above, delta-Y or Y-delta transformers have been used in all cases. Transformers connected in this manner are most usually employed for establishing neutral points on a system. There are a few other combinations that have been used occasionally, such as transformers connected Y-Y with a delta tertiary winding. Where this combination is used, a neutral may be established on both primary and secondary networks, the delta tertiary winding acting as a secondary for either high-tension or low-tension Y, depending on which circuit the fault occurs.

A three-phase, core type transformer connected Y-Y will act as a partial grounding transformer, as the interlinked magnetic circuit, allowing the circulation of flux, performs somewhat the same function as the

FIG. 5—TRANSMISSION SYSTEM WITH TWO GENERATING STATIONS
TRANSFORMER NEUTRALS AT BOTH STATIONS GROUNDED

Current i_s flows as shown if voltage $c d$ is greater than voltage $a b$. If $a b$ is greater than $c d$, then i_s flows in reverse direction.

where no Y-delta connection is available to establish a neutral point for no other purpose than for protection.

The use of the Y-Y transformers is very limited and confined almost exclusively to three-phase core type units as Y-Y connected single-phase transformers invariably have circulating triple harmonic currents between their neutral and the neutral of any other grounded transformers on the system thus tending to cause telephone interference. If there are no other neutrals, the lack of a triple frequency exciting current for these transformers tends to produce triple frequency

voltage between line and ground and to put excessive voltage strains on the system. Transformers connected Y-Y or auto transformers Y-connected, perform no function as grounding transformers unless their neutrals are connected to the neutral of a generator or other Y-connected transformer which would in itself, act as a grounding transformer.

The question of the desirability of limiting the current in the neutral on overhead systems is one on which there is a considerable difference of opinion. There is little question that the greatest protection from high-voltage strains comes from the use of a solidly grounded neutral and that in the long run high-voltage disturbances are the most fruitful source of trouble to the lines and apparatus forming a part of a high-tension system. Modern apparatus is designed to withstand the magnetic and thermal effects of absolute short circuits for the time necessary for relays to clear the circuit and from this standpoint, no real disadvantage is derived from grounding solidly. The dead ground allows high enough currents to flow to make the action of the relays definite and a tendency to greater selectivity results. Where the proper relays are used and short time settings employed, the jolt to the system tending to trip synchronous apparatus out of step, is not a serious matter. In any case, many phase to phase and three-phase short circuits are bound to occur and must be provided for.

The main disadvantage claimed by the advocates of limited currents to ground, are almost entirely those of telephone interference. This is a difficult point to pass upon for all cases, as the relative exposure varies as does the relative activity of the engineers of the telephone company in different territories. There is no question that with a short circuit to ground of heavy current, the acoustic shock on an exposed telephone line is considerable and is to be avoided if possible unless there is a probability of introducing other factors that may be more serious in the long run. Any resistance in the neutral tends to increase the voltage to ground on the other two phases and if this resistance is sufficient, it may produce a semblance of arcing ground effects and the resulting operation over a period of time may cause more acoustic shock trouble than would be the case with a solidly grounded neutral system.

There are different methods employed for limiting the ground current, such as neutral resistance, grounding only one transformer of limited capacity or by the use of a small grounding transformer bank. The grounding resistance for high-voltage transformers is an expensive device and requires considerable attention and maintenance. Various types of resistance have been used such as metallic grid or wound tube resistors, water resistance, concrete and graphite columns, etc. The most satisfactory resistance, however, is either the grid or tube type. Fig. 6 shows a 45,000-volt neutral grounding resistance of the tube type designed for two-minute duty. The individual resistance tubes are

insulated by porcelain between sections and post type porcelain insulators to ground. This completed resistor is insulated for line to neutral voltage and is not only very costly to build but requires considerable installation expense from the fact that it takes up a large amount of room and must be housed.

At the present time, the greater number of high-voltage systems are operating with the neutral solidly grounded at their important generating stations. As an example of such systems, the following may be mentioned:

Alabama Power Company, Georgia Power Company, Southern Power Company, Mississippi River Power Company, Montana Power Company and the Utah Power & Light Company and many others. There are a few high-voltage systems operating with neutral resistance such as the Hydro-Electric Power Commission of Ontario, Niagara Falls Power Company, Niagara & Lockport Power Company and Public Service Company of New Jersey and a few others. The Pennsyl-

FIG. 6—NEUTRAL GROUNDING RESISTANCE FOR 45,000-VOLT SERVICE

vania Power & Light Company, Shawinigan Water & Power Company and the Georgia Power Company operated for several years with a neutral resistance but have since taken them out of service.

The effect on methods of relaying high-voltage systems with limited ground current for the selection and isolation of faults, varies with the extent to which the current is limited.

A ground resistance is often selected of such value as to allow sufficient current to flow to trip overload relays on any feeder and in such cases the current amounts to two or three times full-load current of the largest one. There are no complications with such an arrangement and any type of relay that could be used with solidly grounded neutral, will give equally good results with such a neutral resistance. Systems using high resistance in the neutral and consequent low ground current must resort to special methods of relaying for selective action and there is usually a narrow margin of error allowable in these special cases. The overload relay

on the system. As an example, a grounding transformer on a 110,000-volt network, would be required to furnish sufficient current to trip an overload relay on any 110,000-volt line. As an average value the normal line capacity may be taken as 25,000 kv-a. Under abnormal conditions this line might be required to carry as high as 50,000 kv-a. The overload relay settings should be something above this value, say 60,000 kv-a. The grounding transformer then should be able to pass 60,000 kv-a. equivalent current over the grounded phase. Assuming no reactance in the circuit to the grounding transformer, a Y-delta bank of 6000 kv-a. having 10 per cent reactance would be required, or a 4800 kv-a. bank having 8 per cent reactance. If the longest line from the substation should have a reactance based upon this 60,000 kv-a. of 10 per cent a transformer bank 10 per cent larger of the same reactance would be required.

Such a grounding transformer would give protection equivalent to a system grounded through a neutral resistance of low enough value to allow the same current to flow. If more effective grounding is desired, such as afforded by the solidly grounded neutral system through a large percentage of its generating capacity, a still larger bank must be used or a bank of lower reactance, thus allowing more current to flow.

The advantage in a high-current flowing would seem to be the assurance of a minimum increase in the voltage strain of any part of the system to ground above its normal value. A heavy current flowing from the generator tends by armature reaction to not only reduce the voltage in the grounded phase but also in the other two phases. Full-load current on the generating station flowing to ground through a circuit consisting of step-up transformer, transmission line and grounding transformer would have a fairly low lagging power factor which would have a tendency to drop the voltage of the entire system and in consequence the voltage to ground from the two ungrounded phases to a value little in excess of normal and insure no excessive voltage strains on any part of the system in case of trouble.

It has seemed to the writer that a rule to the effect that ground current at least equal to the full-load current of all the generators should flow. This would give adequate grounding protection to the system and would be a surer rule to follow than merely to allow sufficient current to flow to trip the relays. In some cases this rule would give about the same results as the method of arriving at the size of grounding transformer by a determination of the short-circuit current necessary to trip all the overload relays taking into account multiple circuits, etc.

In case the engineer determines that he wishes to create the same conditions by use of a grounding transformer as he would on a new system by the use of high resistance in the neutral, the grounding transformer would be, of course, correspondingly smaller in capacity as the requirements would be much less.

It will be evident from the foregoing discussion that

the extent to which a system is grounded is usually dependent upon the relation of ground current during a short-circuit to the full-load current of the total generating capacity and not necessarily on whether resistance is used in the neutral or not. We normally speak of a system as grounded solidly if no resistance is used, but many so-called dead grounded neutral systems are grounded through such a small part of their total generating station transformer capacity as to allow less current in terms of a percentage of their total generating capacity to flow, than in some other systems grounded through resistance. The impedance from the generators to the point of short circuit is really the measure of the extent of the grounding.

Adequate grounding for the maximum voltage protection of a system will always be obtained by grounding all the generating station transformers and usually by only one half or less. The grounding of any system at its source of power through all the transformers feeding that system will give ample assurance of no arcing ground effects tending to produce high-voltage strains. There is not as a rule, much object in grounding the receiving stations, practically the only advantage being to insure a neutral point on a station normally acting as both a receiving station and generating station should this be split apart from the main system. There is in fact, some disadvantage in grounding the neutral of several substations fed from the same line or network as a ground at any point on the system draws short-circuit current from every one of these as illustrated in Fig. 4, tending to trip their overload relays or blow their fuses as the case may be, while there is no reason why these stations should be involved in the short circuit at all except for a slight dip in voltage on one phase.

Another method of neutral grounding is by use of a reactance coil between neutral and ground. Such a reactor when designed with an ohmic value such as to allow a current to flow equal and opposite in phase to the charging current to ground of the entire line on which it is connected, is called a Petersen Coil. Papers are being presented at this meeting by Mr. W. W. Lewis and Messrs. J. M. Oliver and W. W. Eberhardt, discussing the action of such a reactor and some operating results from its use. It is probable that such a coil has a very limited field of application and that on comparatively small low-voltage systems or very short lines up to perhaps 110,000 volts where the charging current is of low value and a reasonable percentage of error in tuning will not be likely to allow sufficient current to flow over the insulator to maintain an arc.

CABLE SYSTEMS

The practise in grounding underground cable systems which are usually supplied direct from the generators without the interposition of transformers has in the main, been somewhat different from the practise on overload transmission systems. The greater number

of such systems are operating with the neutral grounded as is the case on overhead lines but a much smaller proportion are operating solidly grounded. It has been quite common practise on such systems to use a small amount of grounding resistance designed to limit the fault current to a value calculated to trip overload relays. A few are operating with solid grounds and a few with comparatively high resistance but the latter are so few in number as to require little comment. No difficulty from telephone interference need be provided for and the object of extremely low fault current being absent accounts for the difference in practise in this respect as the same difficulties are met in selective relaying from the low short-circuit current complicated by high ground charging current.

The most usual method of grounding the neutral of an underground system is to ground one generator through a resistor at each generating station, provision being made to ground any one unit at a time for the sake of flexibility. This practise grew from the fact that in the early days generator wave shapes differed widely and large third harmonic currents were likely to circulate between neutrals if more than one unit were grounded at a time. Modern generators have only a slight third harmonic and such circulating currents will be negligible in most cases. There is, however, no great object in grounding all the generators in a station where a resistor is used as in most cases one unit can provide all the short-circuit current that can pass through the resistor.

Underground cable systems have grown in extent and amount of power handled at a rate that is comparable with the growth of overhead systems and there is a marked tendency just at this time for even more rapid growth. The generating stations being constructed by the larger companies are making the distribution of this power more and more difficult to handle and the voltage of cable distribution is increasing at a rapid rate. At this time, there is a considerable amount of 22,000 to 24,000-volt cable in operation and some at 26,400 volts and one or two installations in the United States of 33,000-volt, 3-conductor cable. There are also one or two installations of 66,000-volt, single-conductor cable being seriously considered. Abroad they have been operating 33,000-volt, 3-conductor cable for sometime, have a 50,000-volt, 3-conductor system about to go in operation and two or three 60,000-volt, single conductor cable systems working. In all of the higher voltage cable installations the neutral has been grounded and up to date, everything above 26,000 volts, has had this neutral solidly grounded. Grounding in this manner definitely insures a limitation of the voltage strain to ground, during faults, not exceeding the leg voltage, which in the present state of the art at least would seem to be extremely desirable.

There seems to be a preponderance of evidence from operation of underground cable systems to indicate that practically all cable faults occur initially as breakdowns

from one conductor to the sheath rather than from conductor to conductor. The limitation of the ground current thus caused to flow by means of resistance in the neutral of the generator or transformer feeding the system and the use of selective relays with extremely short time setting gives a good chance of clearing the trouble before the fault can develop into a phase-to-phase short circuit. Of course the greater proportion of underground cable troubles have developed in the cable joints rather than the cable itself and there is probably considerably greater tendency for such breakdowns to go from conductor to conductor in the joint than in the cable itself, so that we are probably getting a large number of short circuits on our cable system that are not limited by the neutral resistance.

In higher voltage cable such as 26,400 or 33,000 volts, it is problematical as to whether cable breakdowns from conductor to sheath may not develop so rapidly as to produce phase-to-phase short circuits before the switches can open on both ends of the cable even with the minimum time of operation possible with relays. If this proves to be the case the advantage of neutral resistance for limiting the current will be lost and it is probable that better operation will follow from dead grounding of such systems.

Many of the systems now in operation have been laid out for radial distribution and there is a marked tendency toward the use of reactors to limit the current that can be fed into a short circuit on any cable. With such an arrangement it is common practise to use reactors of about 3 per cent reactance based on the rating of the cable. Generating stations of the large capacity now becoming general are not seriously jolted by a short circuit of even 33 times the capacity of a given feeder, especially as the use of bus reactors to partially segregate the station are in quite common use. This again probably precludes the necessity of neutral resistance to limit the short-circuit current.

Several recent large generating stations have been built with a radically new bus arrangement generally referred to as "isolated phase" construction. The main object in such an arrangement is to preclude the possibility of a bus short circuit as all parts of each phase are isolated from the other two phases. The only way in which a short circuit can occur will be to ground and here we obtain a definite advantage from the use of neutral resistance which will limit the possible short circuit in the station to the value of current that will pass through the resistor. In such stations it is common practise to use reactors on all feeders, and in many cases reactors in the generator leads, omitting the use of bus reactors for partial isolation of sections of the station. The only manner in which a station short circuit can occur is through two simultaneous breakdowns to ground which should be an extremely rare occurrence. If neutral resistance is used with such an arrangement of a value sufficient to limit the current to that necessary to trip overload relays or to a value from 1000 to 1500

amperes, it is probable that the heaviest arc that could be expected would be of this value. If neutral resistance were not used, and the practise maintained of grounding one generator at a time, the current in this arc might be as high as 25,000 or 30,000 amperes to ground in some of the larger stations.

At the present time there seems to be little agreement among engineers as to the best method of grounding the neutral on cable systems. There is some tendency toward reducing the resistance in the neutral to a very low value or to leaving it out altogether. The writer hesitates to give an opinion as to which is the better method, but is inclined to think that the omission of resistance is not out of the question, from an operating standpoint, and to feel that lower voltage strains on the complete system would ensue from such a practise, for reasons similar to those discussed for overhead line practise.

Underground cable systems may be grounded in similar ways as discussed for overhead lines and the different methods have a similar influence on the amount and distribution of short-circuit current. The only

FIG. 7—TWO GENERATORS IN MULTIPLE, NEUTRAL OF ONE ONLY GROUND

Line ground at "G". Current flows to line ground from both generators, as illustrated.

distinctive difference lies in the tendency for circulating currents between neutrals of generators where it is usually of less importance than between the neutrals of transformers. It is quite general practise to wind high-voltage generators for Y connection and a ready means of grounding is thus provided.

It was shown in Fig. 5, that a delta-Y transformer at a generating station not only furnishes current direct to a fault to ground from its own generators but in addition may furnish extra current from its function as a grounding transformer from other generating stations. A generator with a grounded neutral will act in a similar manner furnishing current generated internally in the ground phase and also extra current coming from other ungrounded neutral generators. This current flows from the ungrounded neutral generators to ground on the phase in trouble and returns through the neutral of the grounded neutral generator and thence back over the other two phases to the ungrounded neutral generators. (See Fig. 7).

Should it be impracticable or undesirable to obtain a neutral ground by the direct grounding of generator

neutrals, the system may be grounded through Y-delta transformers Y-Y transformers with tertiary delta, zigzag connected transformers, etc., as in the case of overhead systems and the calculation of the rating of such transformers would follow the same general method as outlined.

The effect of different methods of grounding the neutral of a cable system on the function of various types of relays is similar to that on overhead lines although there are in use in some cases certain relay schemes on underground networks not generally considered applicable to overhead line use.

Overload relays on radial feeders are used very extensively and are only affected by the method of grounding to the extent that sufficient current must be available to cause them to trip with a fault to ground. For this purpose provision is usually made in grounding for a current of two or three times the rating of the feeder. As an alternative scheme for radial feeders residual current relays are sometimes used in which case lower ground current is possible as residual current relays may be made more sensitive and set to trip at a lower current.

Relay schemes such as the Merz-Hunter or Cole scheme using split conductor cable for differential protection or using pilot wires, are peculiarly applicable to cable systems and are only affected by the method of grounding by the relation of the sensitiveness of their setting to the current available in case of a fault to ground. While it would seem that lighter ground currents would be possible with these relay schemes, it is probable that more accurate and consistent results would be obtained by working with heavier currents with more available energy for the relays.

Relay schemes such as the case of balanced current relays at the source of power and directional relays at substations require practically as much current as overload relays for selective action.

It has sometimes been argued that higher resistance could be used to ground the neutral of a cable system than a high-voltage overhead line system for the same protection against voltage strains, on the basis that a large amount of energy is stored in the electrostatic capacity of the latter system which tends to produce an oscillatory arc when discharged to ground. Such an argument can hardly be substantiated as the electrostatic capacity of a cable system is much greater at the same voltage than an overhead line system. A 13,200-volt, three-conductor cable at 60 cycles has a charging current per mile to ground of about one and eight tenths amperes, while a mile of 110,000-volt line at 60 cycles has a charging current of only about one half an ampere. It is evident that a 60-cycle system consisting of 13,200-volt cable of the same total mileage as a 110,000-volt overhead line system discharged to ground, would have more than three times the amount of leading current in the arc and a consequent greater destructive tendency.

The presence of the high charging current in an arc from conductor to sheath in an extensive cable system tends to nullify the effect of an unduly high resistance in the neutral for the purpose of limiting the current to a low value, as the charging current does not return through the neutral and hence is not limited by it. A 13,200-volt, 60-cycle cable system with 600 miles of cable would have a charging current to the sheath of over 1000 amperes and on account of the indefiniteness of its path in the system tends to make relaying unreliable. Such a large leading current is almost sure to produce a destructive oscillatory arc unless the short-circuit current combined with it, is of high enough value to stabilize it.

The relay protection of generators is influenced to some extent by the method of grounding the neutral of the system. As units are becoming so large and represent such a heavy investment, it is important that an adequate relay scheme be employed to preserve them from excessive damage resulting from electrical breakdown. It is necessary to open the oil circuit breakers, disconnecting them from the bus and to open their field switches, as well, in the minimum possible time after a breakdown to prevent excessive burning. The relay scheme almost universally employed is to use sensitive quick acting relays, differentially connected to current transformers in the neutral and line

FIG. 8—NEUTRAL GROUNDING RESISTANCE FOR 13,200-VOLT SERVICE

end of each phase. A breakdown to ground causes current to flow back through the neutral current transformer and not through the line current transformer, thus producing differential current to operate the relays. Should such a ground develop close to the neutral end of the winding, this unbalance will be small and if limited by a neutral resistance of high value may delay the action of the relays and extend the damage to the generators.

The most usual type of neutral resistor used for

grounding generator neutrals consists of the grid type similar to Fig. 8. All parts are of standard construction in general use for starting resistors for induction motors and show a high efficiency as to space, first cost, reliability and minimum of maintenance cost. Such resistors can be safely operated for short time duty at temperatures up to 400 degrees cent. and thus absorb a great amount of energy for the space taken up. When it is realized that a 1200-ampere, 6.3-ohm resistor in the neutral of a 13,200-volt generator must absorb 9100 kw.,

FIG. 9—RELATION OF WEIGHT AND COST TO DUTY IN TIME OF A 1200-AMPERE, 5-OHMS, 13,200-VOLT RESISTOR

the importance of working materials to their limit, will be apparent.

A factor of great importance in selecting a neutral resistor is the length of time to be specified for safe operation. The size, weight and cost of such a resistor increases very rapidly with increase in the time for which it is designed. Curve Fig. 9, shows the relation of cost and weight to duty in time of a 5-ohm, 1200-ampere resistor.

Practise varies widely in respect to the time specified for such resistors but the tendency is to make it as short as possible on account of the great saving in first cost. There are many resistors in operation designed for 30-second duty and they range from that all the way up to 10 minutes.

The principles on which the rating should be based are not entirely clear and the issue is usually decided on more or less a compromise basis. The primary function of such a resistor is for the purpose of limiting the current flow to ground for the time necessary to clear the short circuit. Most relay schemes are laid out with the expectation of tripping the oil circuit breakers in a few seconds at most and if they work properly a resistor designed for 30-second duty should have ample margin of safety. If the circuit breaker or relay fails to operate, either due to being out of order or unforeseen distribution of current over several feeders, time must be allowed for the operator to act and 30 seconds is an insufficient time for him to locate the trouble and clear it. The assumption may be made that failure of relay operation is very remote and that in such a case the loss of a resistor may not be serious. This of course,

will depend on the damage that might be expected outside of the loss of the resistor itself.

CONCLUSION

The author has attempted to outline the major problems that present themselves for consideration in laying out a large power system, having in mind the maximum protection feasible for good continuity of service. It is evident that future practise in the design and operation of power systems, both overhead and underground, will be with some form of neutral ground.

There are various methods of grounding in use, such as grounding *Y*-connected generators direct or through resistance, grounding step-up transformers direct or through resistance, the use of step-down transformers grounded direct or through resistance as well as the use of special types of transformers arranged especially for grounding purposes such as *Y-Y* transformers with delta tertiary, zig-zag connected transformers, three-phase core type transformers connected *Y-Y*, etc. all of which were discussed with the purpose of calling attention to the variations in the methods of grounding, which the author has tried to make, leads to the conclusion that effective grounding for desired results can be obtained by any of the methods outlined. The choice of method, then becomes one of convenience and economics.

The one important consideration that the author has laid the most stress on, is the question of the extent to which a system should be grounded for best all around protection to equipment and service. Systems have been loosely spoken of generally as being grounded

solidly or grounded through resistance, irrespective of the fact that a system grounded solidly through a relatively small part of its total step-up transformer capacity may show less effective grounding than another system where low resistance in the neutral is used. The real measure of the extent to which a system neutral is grounded depends upon the relation of ground current flowing to the full-load current of the system.

The important function of the grounded neutral is to limit voltage strains on the system at the time of faults to ground, as experience has shown that such strains are the most fruitful source of extended interruption to service. Modern apparatus is designed to withstand the magnetic and thermal stresses of high current and modern relays will protect service under short-circuit conditions. Voltage strains, however, are difficult to predetermine and expensive to protect against and the neutral ground should be selected with this in mind.

The author has attempted to show that effective grounding for limitation of voltage strains can best be obtained by allowing comparatively heavy currents to flow which means either solid grounding of an appreciable part of the system capacity or a larger part through fairly low resistance.

It has been brought out that from the standpoint of continuity of service, which involves the protection of apparatus and equipment, the successful functioning of relays, etc., that the system with heavy ground current, has many advantages.

Discussion

For discussion of this paper see page 464.

Then
$$I_1 + I_2 = j \omega C_G (E_{13} - E_{23})$$

$$= j \omega C_G (-2j E/2 \sqrt{3})$$

$$= \omega C_G E \sqrt{3}$$
(1)

But $E = \sqrt{3} e$
 in which e = voltage to neutral,

Then
$$I_1 + I_2 = 3 \omega C_G e$$
(2)

That is, by equation (1) the current through the arc is $\sqrt{3}$ times the charging current from one of the two ungrounded conductors to ground when the third conductor is grounded, or by the equation (2) it is three times the normal charging current from one of the three conductors to ground, when none of the conductors is grounded.

FIG. 3—THREE-PHASE SYSTEM WITH REACTOR BETWEEN NEUTRAL AND GROUND. FIGURE SHOWS FLOW OF CURRENTS WITH ARC FROM PHASE 3 TO GROUND

FIG. 4—VECTOR RELATION OF CURRENTS FLOWING IN CIRCUIT OF FIG. 3. ALL ANGLES MARKED BY ARROWS EQUAL 90 DEG.

FIG. 5—FLOW OF CURRENT IN CIRCUIT OF FIG. 3 WHEN THERE IS PERFECT NEUTRALIZATION OF LAGGING AND LEADING CURRENTS

Now if a reactor is inserted between the neutral and ground as in Fig. 3, a current I_L will flow through the reactor and the arc as shown. Vectorially the charging currents of Fig. 1 and the reactor current of Fig. 3 may be represented as in Fig. 4.

If we so proportion the reactor that the current I_L is numerically equal to $I_1 + I_2$, as it is directly opposite in phase, the resultant current through the arc will be zero, and the final flow of current will be as shown in Fig. 5.

The inductance necessary to give this relationship is found as follows:

$$I_L = \frac{e}{\omega L}$$

Let
$$I_L = I_1 + I_2$$

Then
$$\frac{e}{\omega L} = 3 \omega C_G e$$

From which
$$L = \frac{1}{3 \omega^2 C_G}$$

In actual practise there is a watt component of current due to the losses in the reactor and lines, and this

FIG. 6—TYPICAL RELATION OF CURRENTS IN A PRACTICAL CIRCUIT, WITH WATT AS WELL AS REACTIVE COMPONENTS

cannot be balanced out, but exists as a residual current through the arc. (See Fig. 6). In this figure $I_1 + I_2$ is the line charging current and I_L the reactor current, both with a watt component, which add up to give the total watt or resultant current I_R . The reactive components I_A and I_B neutralize each other.

The next question that arises is how to determine C_G , the capacitance from line to ground. The writer has done this for three typical arrangements by means of Maxwell's coefficients. The arrangements chosen are shown in Fig. 7. In each case conductor 3 was grounded. The charging currents found, in terms of the normal three-phase charging current, are as follows:

Case A.

Normal charging current.....	= 1.00
Conductor 1..... I_1	= 1.31
Conductor 2..... I_2	= 1.29

FIG. 7—ARRANGEMENT OF TYPICAL CIRCUITS FOR CALCULATING THE CAPACITANCE TO GROUND BY MEANS OF MAXWELL'S COEFFICIENTS

Case A

Spacing.....	s = 9.8 ft.
Height lowest conductor.....	h = 46.5 ft.
Diameter Conductor.....	d = 0.4 in.

Case B

Spacing.....	s = 6 ft.
Height lowest conductor.....	h = 30 ft.
Diameter conductor.....	d = 0.365 in.

Case C

Spacing.....	s = 10 ft.
Height lowest conductor.....	h = 43.5 ft.
Diameter conductor.....	d = 0.47 in.

Conductor 3 (beyond ground)..... I_3	= 0.51
Ground..... I_G	= 1.45
Conductor 3 (generator side of ground)..... $I_3 + I_G$	= 1.96

Case B.

Conductor 1.....	I_1	= 1.36
Conductor 2.....	I_2	= 1.41
Conductor 3 (beyond ground).....	I_3	= 0.52
Ground.....	I_G	= 1.51
Conductor 3 (generator side of ground).....	$I_3 + I_G$	= 2.03

Case C.

Conductor 1.....	I_1	= 1.32
Conductor 2.....	I_2	= 1.35
Conductor 3 (beyond ground).....	I_3	= 0.48
Ground.....	I_G	= 1.51
Conductor 3 (generator side of ground).....	$I_3 + I_G$	= 1.99

Average

Conductor 1.....	I_1	= 1.33
Conductor 2.....	I_2	= 1.35
Conductor 3 (beyond ground).....	I_3	= 0.50
Ground.....	I_G	= 1.49
Conductor 3 (generator side of ground).....	$I_3 + I_G$	= 1.99

Grounding a conductor other than No. 3 may change the results slightly, and other configurations may give

FIG. 8—CALCULATED FLOW OF CURRENT WITH ONE CONDUCTOR GROUNDED.

Current Values Expressed in Terms of Normal Three-Phase Charging Current.

somewhat different results. The presence of a ground wire will increase the capacitance of the conductors to ground and thereby probably increase the current to ground, and consequently increase I_G .

The results of the preceding tabulation, somewhat rounded off, are shown in Fig. 8. From these figures it will be seen that the capacitance from the ungrounded conductors to ground is about 75 per cent of the normal three-phase capacitance from one conductor to neutral.

Now it is simply necessary to calculate the normal three-phase charging current of the line, and multiply this by 1.5 in order to get the current to ground, in case of a ground on one conductor. Then the neutral grounding reactor should be designed for this current. That is, the ohmic reactance of the neutral reactor is found from the relation:

$$X = \frac{e}{1.5 I_n}$$

in which X = reactor ohms

e = voltage line to neutral

I_n = normal line charging current.

The writer has recently read Technical Report No. 52 of the Report of the Joint Committee on Inductive

Interference of the California Railroad Commission and from this has learned that Mr. L. P. Ferris of that committee worked out a similar relationship between the charging currents of a line with one conductor grounded. Mr. Ferris also refers in his report to some work done a number of years ago by Mr. Geo. S. Humphrey. The figures of both Mr. Ferris and Mr. Humphrey check fairly well with those of the writer as given in the preceding tabulations and in Fig. 8.

The Alabama Power Co. Installation

The system chosen for a trial installation of the neutral grounding reactor is the 44-kv., 60-cycle system

FIG. 9—ONE LINE DIAGRAM OF SYSTEM ON WHICH REACTOR TESTS WERE MADE.

System is 44 kv. 60 Cycles.

of the Alabama Power Company extending from Lock 12 generating station to Montgomery and Selma, Alabama. This is not the main 44-kv. network of this company, but only a small, though important, isolated section. This line is subjected to frequent and severe

FIG. 10 (A)—ARRANGEMENT OF CONDUCTORS ON LOCK-12-VIDA SELMA SECTION.

FIG. 10 (B)—ARRANGEMENT OF CONDUCTORS ON THE VIDA-MONTGOMERY SECTION.

lightning disturbances and has given considerable trouble from this cause in the past.

Fig. 9 shows a simplified one-line diagram of the line. Fig. 10A shows the arrangement of conductors on the Lock 12-Vida-Selma section, Fig. 10B the Vida-

Montgomery section and Fig. 10c the Lock 12-Mitchell Dam section.

Following are the data as to the transmission line conductors, lengths of line, etc.:

FIG. 10 (C)—ARRANGEMENT OF CONDUCTORS ON THE LOCK 12-MITCHELL DAM SECTION

Section	Conductor	Spacing ft.
1. Lock-12-Vida	3/0 Alum. steel core	5-3.5-6.1
2. Vida-Selma	No. 4 Copper	5-3.5-6.1
3. Vida-Montgomery	3/0 Alum. steel core	7-4.5-8.3
4. Lock 12-Mitchell Dam	No. 4 Aluminum	3.5-3.5-5

Section	Length Mi.	Calculated capacitance to Neutral $\mu f.$
1. Lock 12-Vida	27	0.476
2. Vida-Selma	26	0.375
3. Vida-Montgomery	27.8	0.434
4. Lock 12-Mitchell Dam	12.2	0.184

The calculated capacitance is based on the geometrical mean spacing. The normal charging current, assuming balanced line conditions, at 60 cycles and 46,000 volts (the actual operating voltage) is for the total system 14.7 amperes, and for sections 1, 2 and 4 (that is, omitting the Vida-Montgomery line) 10.35 amperes.

In order to take care of various combinations of the present line, and some future proposed extensions, as well as to compensate for possible errors in calculating the current to ground with one conductor grounded, the reactor was designed with taps in approximately 5 per cent steps from 2015 ohms to 811 ohms. The change from one tap to another is made by means of two ratio adjusters with control handles at the top of the cover.

Following is a list of the taps as found by test with the corresponding amperes flowing through the reactor:

Tap	Reactance Ohms	Amperes at 46,000 volts.
1	2015	13.2
2	1915	13.9
3	1825	14.5
4	1735	15.3
5	1630	16.3
6	1567	16.9
7	1492	17.8
8	1410	18.8
9	1357	19.6
10	1276	20.8
11	1207	22.0
12	1140	23.3
13	1088	24.4
14	982	27.0
15	929	28.6
16	870	30.5
17	811	32.7

The reactor has no core. It is oil immersed and water cooled, and designed to operate continuously at 795 kv-a. with 55 deg. cent. rise. In order to prevent eddy losses in the steel tank, the cooling coils are connected as a short-circuited winding in accordance with the Kierstead Patent.¹ The total losses in the reactor at full voltage and maximum current are about 21 kw. Fig. 11 is an external view of the reactor and Fig. 12 an internal view of a similar reactor.

FIG. 11—EXTERNAL VIEW OF NEUTRAL GROUNDING REACTOR

Occasionally there may be a ground on a conductor which is in the nature of a dead ground, for example ground wire against a conductor, conductor down on ground, baling wire connecting conductor and ground wire or conductor and tower, shattered or punctured insulator, etc. In these cases, while the grounding reactor would neutralize the current at the fault, still

1. U. S. Patent 1,394,910.

there would be a large ground current flowing and the system would be in a state of voltage unbalance. It therefore would be desirable to be able to cut out the section of the system in trouble. This is accomplished as follows:

In series with the reactor at the ground end is placed

FIG. 12—INTERNAL VIEW OF NEUTRAL GROUNDING REACTOR

a current transformer of suitable ratio. To the secondary of the current transformer is connected a definite time limit relay, set so that with the minimum current through the reactor the relay will operate in a predetermined time and energize the closing coil of an oil circuit breaker, which closes around and short-circuits

FIG. 13—DIAGRAM SHOWING CONNECTION OF REACTOR AND AUXILIARY DEVICES IN CIRCUIT

the reactor. The system now has a dead or solidly grounded neutral and short-circuit current flows from the power source to the point of line ground. The regular protective relays respond to the short circuit

and the section in trouble is tripped out. This scheme was suggested by Mr. E. W. Pragst.²

Connected to the secondary of the current transformer is a recording ammeter, which gives an indication when current passes through the reactor, and across

FIG. 14—VIEW OF REACTOR INSTALLED

FIG. 15—VIEW OF OIL CIRCUIT BREAKER AND DISCONNECTING SWITCHES USED WITH REACTOR

the red lamp of the oil circuit breaker is a recording voltmeter. By these devices a record may be kept of the operation of the reactor and the short-circuiting breaker. A bell alarm also warns the operator that the circuit breaker has closed.

Fig. 13 is a wiring diagram of the auxiliary connections and shows how the reactor is connected in circuit. Figs. 14 and 15 show views of the apparatus in service.

TESTS

Steady Conditions.

A series of tests was made under steady conditions (no arcs). The Vida-Montgomery section was disconnected and tests made on the remaining sections, *i. e.*, Lock 12-Vida, Vida-Selma and Lock 12-Mitchell Dam. The line was not loaded and the step-down transformers at the ends of and along the line were disconnected.

Fig. 16 shows a diagram of connections for these tests. The readings were taken by means of current and potential transformers connected directly to the high-tension lines. In Table I are summarized and averaged the results of the tests of November 27th and December 4th, 1921, the results in all cases being changed to equivalent figures at 46,000 volts. In tests 5, 6 and 7 the reactor was set at 1735 ohms.

In Table II are summarized the calculated currents for the various conditions. These calculations are based on a capacitance of 1.035 microfarads for the lines in circuit. This would give a normal three-phase charging current of 10.35 amperes, and with one conductor grounded the following amperes in accordance with the previous discussion and as shown in Fig. 8.

I_1 (grounded conductor) $2 \times 10.35 = 20.7$
 I_2 (ungrounded conductor) . . . $1.3 \times 10.35 = 13.5$
 I_3 (ungrounded conductor) . . . $1.3 \times 10.35 = 13.5$
 I_L (beyond ground) $0.5 \times 10.35 = 5.2$
 I_G (current to ground) $1.5 \times 10.35 = 15.5$

FIG. 16—DIAGRAM OF CONNECTIONS FOR TESTS 1 TO 7 INCLUSIVE MADE UNDER STEADY CONDITIONS

Based on a current to ground of 15.5 amperes, the reactor setting should be 1710 ohms. The nearest tap 1735 ohms was used in the tests. Comparing the cal-

TABLE II.
Calculated Currents
Lock 12—Vida, Vida—Selma, Lock 12—Mitchell Dam Lines

Test	Voltage		Current					
	Line to Line	Line to Neutral	1	2	3	N	G	L
1	46,000	26,540	10.35	10.35	10.35			
2	46,000	26,540	20.7	13.48	13.48		15.53	5.18
3	46,000	26,540	20.7	13.48	13.48		15.53	20.7
4	46,000	26,540	10.35	10.35	10.35			
5	46,000	26,540	10.35	10.35	10.35			
6	46,000	26,540	5.18	13.48	13.48	15.3	0.23	5.18
7	46,000	26,540	5.18	13.48	13.48	15.3	0.23	5.18

These values are what would be expected if the three conductors were symmetrically arranged with respect to each other and ground. This not being the case in practise, the actual values should differ somewhat from the above.

culated currents with those measured in tests 2 and 3 we find that the current to ground averages about 18 amperes against a calculated current of 15.5 amperes. Also the current in conductor 1 beyond the ground measures 3.85 amperes against a calculated current of 5.2 amperes. In other words, the current to ground is about 16 per cent greater and that to the grounded conductor about 26 per cent less than calculated.

FIG. 17—C D 57279, TEST 4, LINE CHARGED, NO LOAD, NEUTRAL SOLIDLY GROUNDED

Curve A, Current in Conductor 2.
Curve B, Current in grounded neutral.
Curve C, Voltage between conductors 2 and 3.

This is very likely due to the ground wire, which increases the capacitance of the ungrounded conductors and thereby their charging current to ground. All the ground current, whether it goes directly to ground or first to the ground wire, must eventually return by way of the fault or grounded point on the conductor.

Using the figure of 18 amperes for ground current, then the proper setting of the reactor would be about 1470 ohms instead of 1710 ohms. It will be interesting to compare this figure with that found from the resonance point test reported in the next section.

In test 1 there was measured a voltage from neutral to ground of about 600 volts. This is evidently the residual voltage due to the unbalanced capacitance from the three conductors to ground. If the neutral is grounded a current should flow, due to this voltage. In test 4 (neutral directly grounded) there is a neutral current of about 0.6 amperes and in test 5 (neutral

grounded through reactor) there is a neutral current of about 2 amperes.

From the oscillogram Fig. 17 it is interesting to note

that the neutral current of Test 4 consists of a fundamental and large fifth and seventh harmonics, i. e., the same harmonics as contained in the line charging current. However, in the neutral current of Test 5 (Fig.

18) the harmonics have disappeared, leaving the fundamental only, although the line charging current is practically identical with that of Test 4. The voltage across the reactor (Curve A, Fig. 19,) also contains a fundamental only. The impedance of the reactor to harmonics other than the fundamental is apparently so high that they are wiped out. This conclusion is confirmed by numerous other oscillograms, for example, Fig. 20 curve B shows the current through the reactor for Test 7. This is again a pure sine wave of fundamental frequency.

DETERMINATION OF RESONANCE POINT

The resonance point was determined in two ways:

a. Under normal conditions with no conductors

grounded. In this case the reactor ohms are varied and readings taken of the reactor current, which current in this case is merely a residual capacitance current due to unbalanced capacitance from the three conductors to ground. The resonance point is indicated by the maximum current.

b. When one conductor is grounded. The reactor ohms are again varied and readings taken of current flowing into the ground. This current is the resultant of the leading charging current and the lagging reactor current, combined with the loss current. At the point of resonance this current should be a minimum and consist only of the loss current.

In Table III are given the readings taken with the system unloaded and the Vida-Montgomery section of line disconnected. The results are plotted in Fig. 21 and show that the resonance setting in this case is about

frequency of the circuit consisting of reactor and line capacitance for different settings of the reactor by the

equation $f = \frac{1}{2\pi\sqrt{LC}}$. In Table VIII are summarized the results for the reactor settings corresponding to

and a residual current of 6 amperes circulates through the reactor and arc in series. The resonant circuit has a natural frequency of 66 cycles.

Now suppose that the arc breaks. Then the 6 amperes through the arc cease to flow. The 27 amperes in the reactor-condenser circuit tend to die away by an oscillation at the natural frequency of the circuit, 66 cycles. The potential of conductors 1 and 2 decreases from 1.732 times normal to normal potential (e) above ground. The potential of conductor 3 increases from zero to normal potential (e) above ground. The charges on conductors 1, 2 and 3 adjust themselves correspondingly. This adjustment takes place through a compound oscillation, consisting of a superposition of the normal frequency and the frequency of the resonant circuit.

Fig. 39 illustrates the adjustment of the voltage of conductor 3 to ground when the normal frequency is

loss current). Fig. 38 represents an equivalent circuit. A current of 27 amperes circulates in the resonant circuit consisting of reactor and line capacitance,

tendency for the voltage from conductor to ground to over-shoot in the adjustment to normal value after the arc is extinguished. Mr. L. F. Blume has shown this

in another way by plotting, in polar coordinates, the voltage from neutral to ground (voltage across reactor). Three of his plots are reproduced in Figs. 40, 41 and 42, these being respectively for the 49, 60 and 66-cycle resonance frequencies. The data for these tests are

is 90 deg. ahead of the current. After plotting these to scale it is then possible to determine at any instant the voltage from any point to ground, the ground being considered to occupy successive positions along the spiral. Thus in Fig. 40 at the instant the arc breaks, the voltage from conductor 2 to ground is the distance 2-G, conductor 3 to ground 3-G, and neutral to ground 0-G, conductor 1 being at ground potential. At the instant represented by the first positive peak after the arc breaks the voltages are respectively from conductor 3 to ground 3-G₁, from conductor 2 to ground 2-G₁, from conductor 1 to ground 1-G₁ and from neutral to ground 0-G₁, etc. The voltage from neutral to ground

does not finally go to zero but remains at some value such as 0-G₁₁ on account of the residual ground current which flows through the reactor at all times.

It will be noted that on some of the oscillograms the curve of current in the neutral reactor after the arc breaks apparently decreases to a minimum value and then increases, in other words has an anti-nodal point. Fig. 43 illustrates this nicely. This is because the current in the reactor consists of the oscillation current at the natural frequency of the oscillation circuit, superimposed on the 60-cycle residual ground current. At times their maxima coincide and at other times oppose and the anti-nodes appear at the points of opposition.

We have thus seen that there is the theoretical possibility when the arc-breaks of a voltage building up from the faulty line to ground greater than the normal line to neutral voltage and from the sound lines to ground greater than the normal line to line voltage, in case there is a difference between the resonant and supply

frequencies, *i. e.*, providing the reactor setting is not in exact resonance. Let us see what the tests show in this respect.

Two tests were made at the 982 ohm setting (resonance setting), arcing over a $\frac{3}{4}$ -inch horn gap from conductor 1 to ground. The oscillograms showed the

following: (a) the wave of voltage line 1 to ground went abruptly to zero at the making of the arc and at the breaking of the arc slowly increased to normal. (b) The voltage from line 3 to ground jumped from normal to about 40 per cent above normal (should theoretically go to 73 per cent above normal for a dead ground). (c) The voltage from neutral to ground goes to a value of about 26,800 root-mean-square volts (theroetically should be 26,500 volts) and remains at this value throughout the arc, except that at the first half cycle after the arc is made there is a peak 5 to 20 per cent greater than the steady peak value.

With the 1207 ohm setting (19 per cent unbalance leading) three tests were made, one with an arc over a $\frac{3}{4}$ -inch gap and two over a $3\frac{1}{2}$ -inch gap from conductor 1 to ground. The oscillograms showed (a) wave of voltage line 1 to ground, after the arc broke, went through a slow oscillation increasing above normal then decreasing to less than normal and finally increasing to normal. The maximum was about 35 per cent above normal. (b) The voltage from line 3 to ground increased from normal to a steady value of 50 per cent over normal and for a half cycle to about 70 to 75 per cent above normal. (Should go to 73 per cent above normal as a steady value for a dead ground). (c) The voltage from neutral to ground goes to a steady value of about 26,800 volts, but at the first half cycle after the arc is made there is a peak 15 to 25 per cent greater than the steady peak. Fig. 44, Fig. 45 and Fig. 46 are typical.

As far as the oscillograms are concerned for the limited number of settings tried, there is no overvoltage from any conductor to ground beyond the 73 per cent excess voltage expected from two conductors to ground when the third conductor is grounded. From neutral to ground there is a half-cycle peak about 25 per cent above the line to neutral voltage expected with one conductor grounded. Possibly a further unbalance in the reactor setting would increase these figures somewhat.

Some check tests were made on this point by means of a $12\frac{1}{2}$ -cm. sphere gap, with one sphere connected to ground and the other sphere connected to the line conductor by means of four disk insulators, arranged two in series and two in multiple. Readings were taken for the four tests just described and also for three additional tests in which arcs were made from conductor 1 over $3\frac{1}{2}$ -inch horn gaps and with reactor settings of 1630 ohms (40 per cent unbalance leading), 1207 ohms (19 per cent unbalance leading) and 811 ohms (21 per cent unbalance lagging). The insulator and gap were arranged in some of the tests between conductor 1 and ground and in others between conductor 2 and ground. The sphere gap was set above the expected arcing distance and then screwed down until it arced. The results are given in Table IX.

The figures of Table IX may be discussed as follows: With the sphere located between conductor 1 and

ground and the 1207 ohm setting, the sphere gaps arced over in one case at 9.5 kv. and in another case at 14.5 kv. With the sphere from conductor 2 to ground and the 1207 ohm setting, the sphere gap arced over at 25 kv. in one case and 30 kv. in another case. With the 1630 ohm setting the spheres arced over at 30 kv. and with the 811 ohm setting at 25 kv. Now in order to interpret these results, it would be necessary to know the division of voltage between the spheres and the insulators. This division of voltage depends upon the relative capacitances of the sphere gap and insulators, and on whether the spheres are grounded or not.

that high-voltage switching operations on grounded neutral and ungrounded neutral systems commonly give overvoltages 70 to 80 per cent above normal (theoretically twice normal), also that single-phase short circuits from line to neutral on grounded neutral systems will so distort the voltage triangle as to give an overvoltage between the two unshort-circuited conductors of approximately 80 per cent. Overvoltages less than these values should therefore not be considered excessive.

SHORT CIRCUIT FROM LINE TO LINE

Some tests were made to determine whether or not a

FIG. 43—C D 57257-B. SYSTEM NOT LOADED. VIDA-MONTGOMERY LINE OUT. CONDUCTOR 1 GROUNDED AT LOCK 12 BY 1 AMPERE FUSE OVER 3.5 INCH HORN GAP. NEUTRAL REACTOR SETTING 2015 OHMS

Curve A, Current in Neutral Reactor.
Curve B, Current from Conductor 1 to ground.
Curve C, Voltage between Conductors 2 and 3.

This is further complicated by the fact that the capacitance of the spheres varies with the setting, being greater with smaller settings. It is possible that the division of voltage is such as to give rather high momentary voltage from line to ground. However, if so, this is not sufficiently prolonged to show itself on the oscillograms, and therefore is probably relatively harmless.

FIG. 44—C D 57367-A. SYSTEM LOADED. ALL LINES IN SERVICE. CONDUCTOR 1 GROUNDED AT LOCK 12 BY 1 AMPERE FUSE ACROSS 3.5 INCH HORN GAP. NEUTRAL REACTOR SETTING 1207 OHMS

Curve A, Voltage from Neutral to ground.
Curve B, Voltage from Conductor 1 to ground.

In considering the question of overvoltages, we must remember that all transformers (except those with graded insulation, which at present are not very common) are tested at 3.46 times normal (line to ground) voltage and that the line insulation has this much or greater factor of safety. Also it must be remembered

single-phase line to line short circuit would cause a voltage rise from the unshort-circuited line to ground. The system was not loaded, and the Vida-Montgomery line was out. A single-phase short circuit was placed between conductors 2 and 3 at Vida and the switch closed at Lock 12. Voltage was measured from Line 1 to ground and between lines 2 and 3. Tests were made with the neutral grounded through the reactor, set at 1410 ohms, and also with the neutral solidly grounded. Fig. 47 illustrates the case with reactor, Fig. 48 the case with the neutral solidly grounded. It is interesting to note that in Fig. 47 there is a momentary rise at the make and break of the short circuit of 57 to 58 per cent in the voltage from line 1 to ground. In Fig. 48 there is a voltage rise of about 63 per cent at the break of the short circuit. In other words there is about the same voltage rise whether the neutral is grounded solidly or through a reactor, and this is probably solely due to the distortion of the voltage triangle by the short-circuit current acting on the generator voltage.

SOLID GROUNDS ON LINE

As previously explained when a solid ground occurs on a conductor, means are provided to cut off the sec-

FIG. 49—C D 57262. SYSTEM NOT LOADED. VIDA-MONTGOMERY LINE OUT. NEUTRAL REACTOR SETTING 1735 OHMS. CONDUCTOR 1 SOLIDLY GROUNDED AT LOCK 12 AND REACTOR AUTOMATICALLY SHORT CIRCUITED. THUS PLACING SHORT CIRCUIT ON SYSTEM

tion in trouble at a predetermined time. Fig. 49 and Fig. 50 illustrate the action of this device.

In Fig. 49 the top wave is the current through the reactor due to the solid line ground on conductor 1 at Lock 12. About the middle of the oscillogram the oil circuit breaker closes and short-circuits the reactor, the reactor current going slowly to zero. Short-circuit current then flows (middle wave) until the line is disconnected by the overload relays. The bottom wave is the voltage between conductors 2 and 3 and it is interesting to note that this increases in value to a marked extent, the highest peak being about 90 per cent greater than normal.

In Fig. 50 the middle wave is the reactor current,

which is residual current only until the line ground is thrown on about $\frac{3}{8}$ of the distance from the left end of C D 57302-A. At the end of the two seconds the oil circuit breaker short-circuits the reactor and the reactor current goes to zero (just beyond the center of C D 57302-B.) The short-circuit current then appears in the top wave and is cut off by the line oil circuit breaker near the end of the oscillogram. The bottom wave is the voltage from conductor 1 to conductor 3, which increases during the time of short circuit at the maximum peak about 70 per cent above normal voltage and about 30 per cent during the sustained period of the short circuit.

The relay connected to the secondary of the current transformer in series with the reactor, in this case was

set to operate in two seconds and on about 12 amperes, and in Fig. 50 it will be noted that the reactor oil circuit breaker closed in just 120 cycles after the ground was placed on the circuit.

LIMITATIONS IN USE AND OTHER FORMS OF DEVICE

From the writer's study of this device he is of the opinion that its use will be limited for the present to comparatively low-voltage lines of moderate length, i. e., perhaps up to 66,000 volts, or in a few cases up to

100,000 volts if the length is short. The reason for this limitation is as follows: The current through the reactor is affected by the line reactance. In the case of a short line or low-voltage line this is comparatively small. For example, the Alabama line we have been considering has about 20 ohms reactance, which added to 982 ohms makes an insignificant change in the reactor current. On the other hand a typical 154,000-volt line may require 200 ohms in the reactor and reactance of the line itself may be 150 ohms. It is probable that the residual current in this case would maintain the arc.

In this country the device appears most applicable to those systems which are now operating isolated neutral, and which for some reason connected with the operation or apparatus, do not wish to go to the solidly grounded neutral.

If more than one point is grounded, a reactor must be provided for each point.

If there are no points suitable for grounding, an artificial neutral may be provided by means of a grounding transformer connected Y-delta, the Y being connected to the high-tension line and the reactor placed between its neutral and ground, or the reactor may be connected in one corner of the low-tension delta, or the neutral of the transformer may be grounded solidly and the necessary reactance placed inherently in the transformer between high-tension and low-tension windings.

It has been suggested that with each section of the line a reactor be provided, which may be switched on and off with the line section, thus providing a good balance at all times. Such a reactor may take any of the forms previously mentioned or it may consist merely of a reactor between each of the three conductors and ground, this reactor being designed to balance the capacitance to ground of that section of the line. If one conductor becomes grounded, then the reactor on that phase is short-circuited as well as the capacitance to ground, while on the other two phases the reactor and capacitance as well are raised to the same voltage above ground, and therefore still neutralize each other. By this method, the reactors being in circuit at all times, tend to counteract the normal line charging current, which is sometimes useful for line regulation.

CONCLUSION

Calculations show that the current to ground when one conductor of a three-phase system is grounded is approximately 1.5 times the normal three-phase charging current. Tests on one system show that if the system has a ground wire the ground current is increased about 20 per cent.

About 50 arcover tests were made with the neutral grounding reactor in service, and various settings of reactance both in and out of balance. The reactor satisfactorily performed its function as an arc extingisher. From the tests it would appear that considerable tolerance is permissible in the setting of the reactor.

From the standpoint of voltage stresses, the system with reactor is more like an isolated neutral system than a grounded neutral system, except that the excessive voltage rises due to arcing grounds which occur on an isolated neutral system are eliminated. There is a possibility of overvoltage when the arc breaks due to a difference between the resonant and supply frequencies, providing the reactor setting is not in exact resonance.

The system with reactor has an advantage over the grounded neutral system in that arcs are eliminated without short circuit, which is desirable since short circuits cause mechanical stress to apparatus as well as frequent interruption of service.

In the case of a dead ground on the line, the reactor is short-circuited, the neutral grounded and the circuit cleared by line relays. The device designed to take care of this operation satisfactorily performed its function in test.

In the writer's opinion the device will be limited to comparatively low voltage and short systems for the present, owing to the expense of installing on high voltage and long systems and the difficulty of obtaining a current balance at the arc. Owing to the popularity of and satisfaction achieved with grounded neutral systems in this country, the use of the grounding reactor will probably be limited mainly to isolated neutral systems, whose operation is not satisfactory, but on which for some reason it is not wished to solidly ground the neutral.

On the system tested there was a small current flowing at all times to the solidly grounded neutral, due to unbalanced line capacitance. This current contained fifth and seventh harmonics. The neutral reactor caused this current to increase appreciably but the fifth and seventh harmonics were totally eliminated.

The writer wishes to acknowledge the hearty co-operation of Mr. J. M. Oliver, Operating Engineer of the Alabama Power Company, and his assistants, also that of Messrs. M. A. Rusher and C. L. Schermerhorn of the General Engineering Laboratory of the General Electric Company in making the tests.

Operating Performance of a Petersen Earth Coil

BY J. M. OLIVER and W. W. EBERHARDT

Associates, A. I. E. E.

Both of the Alabama Power Co., Birmingham, Ala.

Review of the Subject.—This paper is a report on the Alabama Power Company's operating experience with a Petersen Earth Coil installed between the neutral and ground of a 120-mile, 44,000-volt, 3-phase, star-connected, 60-cycle system.

A Petersen coil is essentially an inductive reactance of such value as to maintain resonance with the capacitance of the system to ground at the fundamental system frequency. With a ground on one wire the current through the fault is reduced to such a low value as to prevent maintenance of an arc. Therefore, on the assumption that the majority of phase-to-ground short circuits start as insulator flashovers, the installation of such a device as a Petersen coil which would snuff out flashover arcs should considerably reduce the number of interruptions to the line.

By means of proper relaying, cases of trouble outside of the operating sphere of the Petersen coil, such as phase-to-phase short circuits and solid grounds have also been successfully taken care of.

Previous to the installation of this coil numerous interruptions to service were experienced on this system during lightning storms, which are unusually severe in the territory covered by these lines.

A PETERSEN Earth Coil, or neutral grounding reactor was installed on the Alabama Power Company's Lock 12-Vida 44,000-volt system on October 12, 1921, and, with the exception of short intervals during testing and construction periods, has been in continuous service to date. Although Petersen coils have been in use in Europe for sometime, the Lock 12 installation is perhaps the first one in this country which has been in actual continuous operating service for a considerable length of time, and it has consequently aroused a great deal of interest.

The purpose of this paper is to give a description of the Lock 12 installation and a complete account of its operating performance to date. The theory of operation of the Petersen coil together with a report of tests made at Lock 12 on December 3-4, 1921, and January 18-19, 1922, in conjunction with the General Electric Company, are presented in a companion paper by Mr. W. W. Lewis.

DESCRIPTION OF LINES

The Lock 12-Vida 44,000-volt system is a three-phase, star-connected, 60-cycle system, consisting of a main line from Lock 12 to Vida having tap lines to Mitchell Dam and Clanton, an east branch from Vida to Montgomery, and a west branch from Vida to Marion as shown in the single-line diagram Fig. 1.

These lines are not a part of the main 44,000-volt network, but form a separate and very important system, as they are the main source of supply to the cities

1. So named after its inventor Prof. W. Petersen, of Darmstadt, Germany.

Presented at the Spring Convention of the A. I. E. E., Pittsburgh, Pa., April 24-26, 1923.

This system, therefore, offers an ideal location for a trial installation of the coil.

Since the installation of the coil the number and duration of interruptions due to lightning flashovers have been reduced by 83.5 per cent and 94 per cent respectively. Several doubtful actions, however, have occurred during switching operations, indicating the presence of unusual phenomena. By proper relaying it is hoped to prevent the recurrence of such action. Further tests are also contemplated to investigate the unusual phenomena accompanying certain operating conditions.

of Montgomery, Selma, Marion and Clanton, having a combined population of over 60,000. The maintenance of service to these lines consequently is of prime importance, and the application of any device such as a Petersen coil, which would reduce the number of inter-

FIG. 1—LOCK 12—VIDIA 44,000-VOLT SYSTEM

ruptions could be well demonstrated here. Furthermore, the territory covered by this system is subjected to lightning storms of unusual frequency and intensity resulting in numerous line outages due to insulator flashovers, the very trouble from which the Petersen coil promises relief. These lines were, therefore, selected as the most ideal location for a trial installa-

tion of the Petersen coil on the Alabama Power Company's system.

The physical characteristics of the lines comprising the Lock 12-Vida system are as follows:

Line	Length miles	Number of circuits	Conductor	Spacing	Insulation
Lock 12-Vida	27.0	1	(168,000 cm. A1. steel core)	5-3.5-6.1	50-kv. pin type
Mitchell dam tap	12.0	1	No. 4 Alum.	3.5-3.5-5	50-kv. pin type
Clanton tap	1.3	1	No. 4 Cu.	5-3.5-6.1	50-kv. pin type
Vida-Montgomery	27.8	1	(168,000 cm. A1. steel core)	7-4.5-8.3	4 O. B. suspension units
Vida-Marion	52.0	1	No. 4 Cu.	5-3.5-6.1	50-kv. pin type

These lines are all of pole construction with wooden cross arms giving conductor spacings as shown in Figs. 2, 3 and 4 of the various lines. There are no transpositions in any of the lines.

All the lines, with the exception of the Lock 12-Mitchell Dam line, are equipped with one 3/8-in. 7-strand steel, overhead ground wire grounded at each

FIG. 2—LOCK 12—VIDA-SELMA LINE, FACING SELMA
FIG. 3—VIDA-MONTGOMERY LINE, FACING MONTGOMERY
FIG. 4—LOCK 12—MITCHELL DAM LINE, SELMA-MARION LINE

pole. The insulator pins are not grounded, but the cross braces at each pole are connected to the grounding wire. On the Lock 12-Mitchell Dam line, which has no overhead ground wire, a lateral grounding wire runs up each pole to the top insulator pin.

This system is fed from Lock 12 through a 9000-kv-a. transformer bank consisting of three 3000-kv-a. single-phase, step-up transformers, connected 6600 volts delta on the low-tension side to 44,000 volts star on the high-tension side. The Petersen coil is connected between the neutral of the 44,000-volt winding and ground, as shown in Fig. 5.

DESCRIPTION OF PETERSEN COIL

The Petersen coil is an oil-immersed, water-cooled, reactor without core having a continuous rating of 795

kv-a. at 26,540 volts, 60-cycle, with a 55 deg. cent rise. The reactor is designed to have a reactance of 2015 ohms with 5 per cent taps ranging down to 811 ohms. Ex-

FIG. 5—LOCK 12—PETERSEN COIL INSTALLATION—SCHEMATIC DIAGRAM OF CONNECTIONS

ternal and internal views of the reactor are shown in Figs. 6 and 7 respectively.

The numerous taps on the reactor are equipped to take care of various combinations of the present lines in service and proposed future extensions. The Petersen coil operates on the principle of an inductive reactance resonated at the fundamental system frequency with the capacity reactance of the system to ground—hence, for every setup on the system involving different combinations of lines in service, a correspond-

FIG. 6—OIL-INSULATED, DISK-COIL, WATER-COOLED REACTOR

ing value of inductive reactance will be required equivalent to the capacity reactance of lines in service.

The setting of the reactor to maintain resonance is conveniently accomplished by means of two ratio adjusters, with control handles extending through the tank cover, enabling adjustments to be made in but a few minutes time.

several flashovers occurred (July 7, August 25, 1922 and Feb. 23, 1923) on the 44,000-volt bus insulators at Lock 12, when the line switch was opened automatically or by hand. At these times the Petersen coil was in service. Whether it was in any way responsible for the flashovers, is not known, but, as a precaution against similar troubles in the future, the line relays have been electrically interlocked with the control circuit of the grounding switch as shown in Fig. 5, insuring that the grounding switch is first closed before the line switch can open on relay action. This interlocking, however, has the disadvantage of slowing up the relay operation on phase-to-phase short circuits. The operators likewise have instructions to always close the grounding switch before doing any line switching.

OPERATION

Table I is a log of all the Petersen coil operations, from October 12, 1921, to March 1, 1923, as read from the charts of the combined graphic ammeter and voltmeter. From October 12th to November 30, 1921, the graphic ammeter was equipped with a 30-ampere coil instead of a 5-ampere coil, which would give only 1/16 inch deflection on the chart for 22 amperes. Since flashovers last only 5 to 15 cycles, it is thought that during this period the Petersen coil may have functioned on a flashover to which the ammeter did not respond. One severe lightning storm occurred in the period during which no operations were recorded. All indications from December 1, 1921 to date have been with a 5-ampere ammeter coil in service.

FLASHOVERS

A study of the log showed that the majority of operations gave indications of only 5 to 10 amperes, whereas, for a clear cut flashover to ground with all lines in service, the neutral current should be 22 amperes. These low indications may have been due to

1. A time lag in the swing of the ammeter pen, the arc having been snuffed out before the pen accomplished its full swing.

2. A resistance ground instead of a clear ground on flashover due to the fact that the insulator pins are not grounded.

The latter is a plausible explanation of the low-current indications and it is believed that, for positive action of the Petersen coil, the insulator pins should be grounded.

A summary of the operations is shown in Table II where it is noted that there have been 168 flashover indications, which seems rather high for the period covered. It may be that all of the low-current indications are not the result of flashovers, but if such is the case it would be difficult to draw a dividing line between the true flashover indications and those due to other causes. The ammeter scale is considerably contracted from 0 to 5 amperes whereas above 5 amperes the unit scale divisions are more uniform, making an ampere division above 5 amperes on the chart nearly equal to

the division representing 0-5 amperes. Since the 5 ampere indications are comparatively small, a tentative classification has been made in Table II of the flashover indications of 6 amperes and above, and those below 6 amperes.

FAULTY OPERATIONS

In all there were only two operations which could be strictly classed as faulty operations. These occurred on December 26th at 5:34 p. m., and on August 8 at 4:55 p. m. when the flashovers held on long enough to close the grounding switch and cause the overcurrent relays to open the line. The line in each case went back in service properly, indicating that the trouble was not a solid ground, but a flashover which the Petersen coil evidently failed to clear.

SOLID GROUNDS AND PHASE-TO-PHASE CIRCUITS

The summary shows that there were a total of 29 cases of solid grounds and phase-to-phase short circuits due to line, transformer, and bus trouble, which are outside of the operating sphere of the Petersen coil. All of these cases, however, were successfully cleared by the line relays. Of these operations, however, three are considered doubtful—namely, on July 7th, August 25th and February 23rd when, after the line switch opened, a string of insulators on the 44-kv. bus between the transformer and the line switch flashed over. The flashover in each case was across 5 units of O. B. suspension insulators, indicating the presence of an unusually high voltage. The insulator units all meggered well on being tested after the trouble, indicating that the troubles were not due to insulator failures. It seems that some high-voltage transient was introduced in these cases due to the disconnection of the line capacitance. It is proposed to make further tests to verify this point. As stated before, all switching, both hand and automatic, is now being done with the grounding switch closed—that is, with the reactor out of service.

TRUE FLASHOVERS IN WHICH GROUNDING SWITCH CLOSED

There were seven operations in which the grounding switch closed, but no line switch opened, and no disturbance occurred on the system. As the closing of the grounding switch seemingly indicated a solid ground on the system, the only explanation for these operations is that a flashover or solid ground held on long enough (two seconds) to cause the definite time limit overcurrent relay to operate, but cleared before the contacts of the grounding switch closed. These operations are all considered correct as there were no interruptions to service.

NEUTRAL CURRENT INDICATIONS ON SWITCH OPERATIONS

There were twenty cases of reactor current indications coincident with switching operations on the lines under conditions when the neutral current must have been zero. These indications may have been due to the

TABLE I
ALABAMA POWER COMPANY—LOCK 12 GENERATING STATION
Log of Petersen Coil Operation

Date	Flashover to ground	Solid grounds	Phase-to phase short circuits	Automatic switch operations	Reactor current amperes	Operation	Nature of trouble and remarks
1921 Nov. 16			11:28 a.m.	#206 opened	0	Correct	A surge occurred on the Montgomery line, and Line Switch #206 at Lock 12 opened automatically. Cause of trouble was the failure of a transformer at Prattville approximately 15 miles northwest of Montgomery. The fuses at transformer failed to clear trouble, and a single-phase line-to-line short circuit developed. The Petersen coil is not supposed to function under such conditions, so the line switch operation was correct.
Dec. 1	10:40 p.m.			208 closed	21	Correct	Weather cloudy. Cause unknown. No surge or outage occurred. Evidently a flashover or solid ground occurred and held on for two seconds at which time closing relay of the grounding switch was energized, but the flashover cleared before the grounding switch closed its contacts.
Dec. 2					7		Occurred 12:40 p.m. when switch #1802 was closed. Evidently due to switch contacts not closing together.
Dec. 8	5:18 p.m.				13	Correct	Weather cloudy. No outage or surge occurred.
Dec. 8	5:20 p.m.			208 closed	22	Correct	Weather cloudy. No outage or surge. Evidently a flashover or momentary ground occurred and held on long enough (2 sec.) to cause grounding switch to close, but cleared before grounding switch completed its closing operation.
Dec. 8	5:22 p.m.				15	Correct	Weather cloudy. No outage or surge occurred.
Dec. 8	6:00 p.m.				15	Correct	" " " " " " " "
Dec. 8	6:12 p.m.				15	Correct	" " " " " " " "
Dec. 11	9:18 a.m.			208 closed	18	Correct	Cause unknown. No lightning or rain occurred during this period. The ammeter pen would swing up to values noted, the grounding switch would close, but not latch, and then operation would repeat. On the fourth operation at 9:30 a.m. the grounding switch latched, but the current in the reactor held on at 6 amperes. No surge, however, occurred due to a short circuit. It is believed that the grounding switch blades did not make good contact, which were consequently changed two days later, and carefully checked to see that good contact was made. No cause could be found for the operation, but at the time, switching was being done at Prattville on the Montgomery section of the line. No arcs of unusual length were noted, however, when the air break switch at Prattville was opened. Considered correct as no outage or surge occurred.
	9:20 a.m.			208 closed	17	Correct	
	9:25 a.m.			208 closed	20	Correct	
	9:30 a.m.			208 closed	19	Correct	
Dec. 17	8:55 a.m.				8	Correct	Weather fair. No outage or surge.
Dec. 17	9:00 a.m.				12	Correct	Weather fair. No outage or surge.
Dec. 26	5:34 p.m.			208 closed 206 opened	25	Faulty	Weather cloudy. Surge occurred when grounding switch closed. The line Switch opened automatically, but was reclosed 2 minutes later and remained in o. k. indicating that disturbance was a flashover and not a solid ground.
1922 Jan. 6		1:10 a.m.		208 closed 202 opened	21	Correct	Disturbance occurred when 206 was opened by hand to take line out of service to change a bad 44-kv. bushing on the transformer bank at Lock 12. Bushing, however, failed when line switch was opened resulting in a phase-to-ground short circuit. The grounding switch then closed automatically, and trouble was cleared by automatic operation of switch on low tension side of the transformer bank.
Jan. 16	2:35 p.m.				11	Correct	Weather fair. No outage or surge.
Mar. 3			1:05 p.m.	1802 opened	2	Correct	Switch 1802 first opened auto. When 1802 was reclosed #202 opened auto. Then 202 was closed and 1802 again opened auto. Patrolman later reported a tree down across Mitchell Dam Line.
			1:35 p.m.	202 "	10	"	Recorded at 12:25 p.m. when 1810 and 1812 were opened and reclosed at Vida by hand on prearranged switching orders.
Mar. 8			1:40 p.m.	1802 "	7	"	Lightning. Voltage surged from 115 to 108 volts. Switch 1812 reclosed after one minute. Evidently phase-to-phase short circuit. Reactor current probably due to switch operation.
Mar. 14			5:35 p.m.	1812 opened	5	"	Recorded at 7:55 a.m. when 1810 was closed at Vida after a prearranged interruption to Montgomery.
Mar. 26					7		Severe lightning. No outage or surge.
Mar. 31	5:00 a.m.				19	"	" " " " " " " "

July 23	12:20 p.m.				4	Correct	Weather cloudy. " " " " " " " "
July 24	10:15 a.m.				5	Correct	" " " " " " " "
July 26					8		At 6:30 a. m. Mitchell Dam operator reported that they were only receiving single-phase power. The chart showed a reactor current of 3 amperes which held on until 7:00 a. m. when switch 1802 was opened by hand when a current of 8 amperes was recorded due to switching. Upon patrolling line, a lug on a test loop was found burned in two and remaining in the clear but opening the line.
	1:40 p.m.				6	Correct	Lightning. No outage or surge.
	2:05 p.m.				6	Correct	" " " " " " " "
July 27		5:32 p.m.	5:28 p.m.	1802 opened	7	Correct	Stormy. Started as a phase short circuit, which caused #1 phase conductor to burn in two and fall on ground on Mitchell Dam line at pole 98. Line was plugged back four times in sectionalizing for trouble. At 5:55 p. m. it was decided to operate with the one phase grounded with Petersen coil in service. Grounding switch was blocked so it couldn't close and short out the coil. At 6:12 p. m. a bushing failed on switch 1802 due, no doubt to full line voltage having been imposed on the two ungrounded phases. The Mitchell Dam line was then taken out of service.
				208 closed			
		5:32 1/2 p.m.		1802 opened	22	"	
				208 closed			
		5:33 p.m.		1802 opened	22	"	
				208 closed			
		5:33 1/2 p.m.		1802 opened	22	"	
				208 closed			
July 27		10:40 p.m.		1802 opened	22	"	When Mitchell Dam was closed back in after above switch trouble was repaired, it again opened automatically. This time a line conductor (phase 2) was found burned in two and on the ground at pole #98. This is the same place where #1 phase burned in two at 5:32 p. m. Conductor on Phase #2 was evidently badly burned on the line to line short at 5:28 p. m.
July 28	2:10 p.m.				9	"	Lightning. No outage or surge.
	2:30 p.m.				5	"	" " " " " " " "
July 30					6		Recorded at 10:50 a. m. while switching was being done at Vida.
July 31					5		Recorded at 11:10 a. m. when #1802 was opened by hand. Current held on until 1802 was closed again at 11:32 a. m.
			12:12 p.m.	206 opened	5	"	Lightning. Voltage surged from 114 to 103 volts. Probably a phase-to-phase short circuit as 208 did not close. Reactor current probably due to opening of 206. Switch 206 closed back in o. k. after interval of 2 minutes.
			1:28 p.m.	1802 opened	6	"	Lightning. Voltage surged from 115 to 110 volts. Grounding switch 208 did not close, therefore, probably a phase-to-phase short circuit. Reactor current probably due to opening of switch 1802. Line was closed back in o. k. 12 minutes later.
					5		Recorded at 1:40 p. m. when 1802 was closed back in.

Oct. 29	5:25 p.m.				5	Correct	" " " " " "
Nov. 5	1:35 p.m.				10	Correct	Weather fair.
The Petersen Coil was out of service from November 16, 1922 to January 13, 1923, while the Transformer Bank was being moved to a new location in the Lock 12 Power House.							
1923 Jan. 14					8		Occurred at 8:50 a. m. when switch 1810 was opened to cut out Vida-Montgomery line. Current held on at an average of 7 amperes until switch 1810 was reclosed. It is possible that pen may have been stuck.
	6:26 p.m.				10	Correct	Cloudy. No outage. Surge 108 to 104 volts.
Jan. 19	4:20 a.m.				6	Correct	Cloudy. No outage or surge.
Jan. 23		9:04 a.m.		208 closed	16	Correct	Raining. No outage or surge. Seems that flashover held on long enough to cause 208 to operate, but cleared before contacts of 208 closed.

TABLE I (Continued)

Date	Flashover to ground	Solid grounds	Phase-to-phase short circuits	Automatic switch operations	Reactor current amperes	Operation	Nature of trouble and remarks
Feb. 23		6:56 p.m.		#206 opened 208 closed 202 opened	27	Doubtful	A light surge was noticed on the line one minute earlier—at 6:55 p. m. At 6:56 p. m. a flashover occurred on 44-kv. bus between transformer and line switch #206. One unit of a five unit string of O. B. disk insulators was shattered but not punctured.* Insulators were meggered afterwards and found to be in good condition indicating that trouble was not an insulator failure. The bus conductors near the point of flashover were badly pitted on all three phases indicating that a phase-to-phase short circuit developed. Sequence of switch operations is not known, but as there was no cause for line switch 206 to open on bus trouble, it is thought that 206 opened first on some initial case of line trouble, as indicated by surge at 6:55 p. m. Then due to perhaps a switching transient, the bus flashed over and this secondary trouble was then cleared by the low side transformer switch #202. It is thought that grounding switch #208 did not close until after the 44-kv. bus trouble developed. The line was patrolled afterwards, but no evidence of trouble was found. Line was closed back in o. k. 1 hour and 26 minutes later.

*This unit was next to the bus conductor.

failure of all three poles of the oil circuit breaker to open or close simultaneously, thereby causing the system neutral to shift somewhat due to a momentary unbalanced electrostatic condition on the line. It is proposed to make further tests to verify this point.

GROUNDING PHASE OPERATION

As noted in Table I operation with one phase conductor on the ground was attempted on July 27, 1922, in the effort to continue service until the line could be more conveniently taken out for repairs later on. After 17 minutes of grounded phase operation a switch bushing failed on one of the ungrounded phases, due no doubt to the imposition of full line voltage to ground on these phases. Our experience in this one case indicates that, although the Petersen coil may prevent arcing grounds on grounded phase operations,

it is hardly safe to take the risk, as the imposition of full-line voltage to ground on the ungrounded phase for a considerable length of time will tend only to aggravate the trouble.

The Petersen coil was designed for continuous service to take care of possible grounded phase operations in emergency. With grounded phase operation eliminated, the Petersen coil need only have approximately a 2-minute rating, and could be built at a cost much less than that of a continuously rated coil.

COMPARISON OF OPERATION WITH AND WITHOUT THE PETERSEN COIL

In the ultimate analysis the value of the Petersen coil will be determined by its service record, and no better conclusions can be drawn than by a direct comparison of the interruption records of similar

periods and conditions, with and without the Petersen coil in service.

For such a comparison we have taken the period, January through September 1921, as covered by Table III before the Petersen coil was installed, and a corresponding period in 1922, as covered by Table IV, when the Petersen coil was in service.

In 1921 there were 43 interruptions due to lightning causing the line to be out of service a total of 230 minutes. In 1922 there were only 7 cases of interruptions due

quently gave no indications on the Petersen coil chart for this day. The interruptions of 79 and 62 minutes respectively in July and August were due to insulator flashovers on the 44 kv. bus at Lock 12. These flashovers seemed to develop after the line switch opened, so there is some doubt as to the origin of the trouble.

Oil Switches. The interruptions charged to Oil Switches in July and August were all due to mechanical trouble in the switch mechanisms.

to lightning, or a reduction of 83.5 per cent, with the line out of service a total of only 14 minutes, or a reduction of 94 per cent.

In 1922 there were, however, more cases of trouble due to other causes, but that the majority of them were independent of the Petersen coil performance can be shown as follows:

Transformers. The interruption of 343 minutes due to transformer trouble occurred on January 21 while short-circuit tests were being made at Lock 12. A transformer failed due to short-circuit stresses. The Petersen coil was out of service during the tests.

Conductors. The interruptions of 2 minutes and 47 minutes respectively in March and July charged to conductors, was caused in each case by a tree falling down on the line.

Insulators. The ten interruptions in March all occurred on the 7th when an insulator pulled loose from its pin and swung into the phase above. This resulted in a phase-to-phase short circuit and conse-

CONCLUSIONS

The Petersen coil has decidedly reduced the number of interruptions due to insulator flashovers during lightning storms. It has, however, produced several actions which need further investigation, namely, the bus insulator flashovers which occurred when line switching was done with the Petersen coil in service. It is proposed to make further tests on such actions to see if high voltages are actually produced.

Points, which operating experience with the Petersen coil has thus far proven are:

1. All insulator pins should be grounded in order to secure the best positive action on the coil.
2. All switching, both hand and automatic should be done with the coil out of service—namely, with the system neutral solidly grounded.
3. Grounded phase operation is not advisable.

Discussion

For discussion of this paper see page 464.

Present Day Practises in Grounding of Transmission Systems

First Report of Subcommittee on Grounding of Protective Devices Committee A. I. E. E.

THE Subcommittee on Grounding of Systems of the Protective Devices Committee was created on October 14th, 1921, "To Study the special problems and applications of grounding of systems." In order to fulfill its function, the subcommittee prepared an inquiry on the general subject of grounding which was sent out through its members to representative operating companies throughout the United States and Canada.

Thirty-six replies were received to this inquiry covering 6,371,850 kv-a. of generating capacity and 31,408 miles of transmission lines. The data obtained in this manner form the basis of this first report of the subcommittee.

On account of the complexity of the various systems which are not only operated at various voltages but also inter-connected with each other, it has been found necessary to establish some sort of arbitrary classification. Accordingly in the analysis following each transmission section of each company which operated at one voltage has been designated as a system, *i. e.*, each company is said to operate as many transmission systems as it uses different voltages. On this basis the 36 companies reporting operated a total of 111 systems. This definition of a system will be used throughout the report.

With respect to the grounding of neutral problems, transmission systems divide themselves into two main classes, each of which has its own peculiar characteristics radically different from those of the other. The two classes included are:

- I—Systems Transmitting at Generated Voltage
- II—Systems Transmitting at Higher Than Generated Voltage

In the following report these two classes of systems will be treated in detail separately:

I—Systems Transmitting at Generated Voltage

BY W. W. WOODRUFF,

Associate, A. I. E. E., Field Engineer, Philadelphia Electric Co.

Twenty companies reported on 31 systems transmitting power at generated voltage, the total generating capacity of which companies was 2,387,500 kv-a. and the total mileage was 8627.

In analyzing the information received, it is intended to point out the features upon which there is general agreement and to indicate those that require further

Presented at the Spring Convention of the A. I. E. E., Pittsburgh, Pa., April 24-26, 1923.

discussion. On account of the complexity of the various systems considerable difficulty has been experienced in getting them on a comparable basis. In order to arrive at some definite means of comparing the different systems, it was endeavored to segregate the actual kv-a. generator capacity of each property, in accordance with the method of grounding employed in the generating station, grouping all capacity of each system, regardless of voltage, in accordance with whether it was dead-grounded, grounded through resistance or ungrounded.

In Fig. 1 the result of this classification is shown very clearly.

It is evident from inspection that by far, the greater

FIG. 1

portion is grounded through resistance, that the ungrounded system comes next in importance, while the dead grounded system is in the minority. The figures are:

- Grounded through resistance. .1,901,700 kv-a.
- Ungrounded..... 371,300 kv-a.
- Dead Grounded..... 114,500 kv-a.

These figures do not include those systems which transform practically all the power generated to a higher voltage.

This analysis leaves no doubt that the preponderance of opinion is in favor of operating with a neutral grounded through resistance. This generalization must

be understood to apply only where the generated voltage is used on the distribution system.

The main points brought out by the analysis of the information received are as follows:

a. The tendency is toward operation with some form of grounded neutral.

b. The abolition of the free neutral and adoption of the grounded neutral has decreased cable troubles.

c. The general opinion is in favor of grounding the neutral through a resistance, in preference to the dead-grounded.

d. The relation between voltage and value of neutral resistance as indicated by calculation of the "volts per ohm" shows that a fairly consistent policy has been followed in proportioning the neutral resistance for the various voltages.

e. Where ground relays are used the neutral resistance is generally higher than for systems relaying on phase relays.

f. The cast iron grid resistance box mounted on insulators appears to be giving satisfactory service.

In going over the information submitted, it is interesting to note the changes that have come about with the growth of the properties, and the relative importance of certain engineering features as compared with the amount of generating capacity.

In general, the systems when comparatively young and with small generating capacity were operated without grounds—and the tendency seems to have been to avoid the grounded neutral wherever possible. This policy seems to have been dictated by the desire to prevent accidental grounds from developing into short circuits.

It should be borne in mind that at the time these systems were built, the protective devices for opening breakers and the circuit breakers themselves had not reached their present state of development and that consequently a short circuit was very likely to be accompanied with quite unpleasant results in the stations.

So long as the systems remained comparatively small, and the greater part of the distribution system consisted of aerial feeders, there seems to have been very little reason to complain of the ungrounded system. However, with the increase in the amount of underground work, and consequently the electrostatic capacity of the system, it began to appear that such grounds as did occur had a very disturbing effect, causing surges and high-frequency oscillations that were communicated to otherwise unaffected parts of the system, and furthermore, that the actual location of the circuit in trouble was very difficult.

As the systems continued to increase in size it began to appear that the ground current, or system charging current, had reached such a magnitude that the arc formed at an accidental ground was very destructive and would burn the cable at the fault sufficiently to establish a short before the faulty section could be isolated.

With the advent of this contingency the supposed advantages of the isolated system, in so far as they pertained to the prevention of short circuits disappeared and the tendency in several instances was to go to the other extreme and dead ground the neutral without resistance.

In general, it may be said that dead grounded systems operated quite successfully for a time, but it became evident with the increase of generating capacity that such grounds and short circuits as occurred began to cause disturbances of increasing severity.

While these data do not prove the point, it is known that the first step taken to minimize the effects of the severe short circuits was to place reactors first in the generator leads and then in the outgoing feeders. Eventually, however, the increasing severity of the disturbances caused by grounds led to the insertion of resistance in the neutral connection.

The question naturally arose as to the amount of resistance required and apparently the first tendency was towards the insertion of so great a resistance, that the ground current was decreased to the neighborhood of the normal current of the feeders. Under this condition, it developed that very frequently when a ground occurred, the combined ground and load current was insufficient to operate the overload relays. In consequence, the tendency was again towards decreasing the resistance to a point where the ground current would be sufficient to operate the relays regardless of the extent to which the particular feeder happened to be loaded.

This policy naturally brought the conditions back towards the point where ground currents were of such magnitude that considerable disturbance resulted from them, but the general opinion seemed to be that this condition with the certainty of the ground being automatically isolated, was preferable to the conditions of the less certain operation of the breakers. However, attention naturally turned towards methods of decreasing of the current disturbances, so that at the present time the tendency appears to be towards the increasing of this neutral resistance with the addition of various types of ground detecting, and reverse power relays to automatically isolate any feeder that is defective.

In comparing the replies from the different companies, it is quite interesting to note the relation between the magnitude and nature of the system and the amount of attention which has been given to the matter of grounding. Even with several of the larger companies, where conditions are such that a considerable portion of the construction is aerial, no very careful attention seems to have been given to the system of grounding, or at least to a comprehensive scheme of relay protection, while those companies whose systems are almost entirely underground, and which have a very high standard of operating performance, have gone into the matter in considerable detail.

As to the systems of protections used there seems to be very little standardization of practise except that there may be said that at present the majority of properties rely on the ground current being of sufficient magnitude to trip out the circuit breakers of the affected feeder. This, of course, applied mainly to those systems where there is no provision for ground detecting relays.

However, where ground relays are provided, there is wide divergence in the methods employed, both for the operation of feeder switches, and the making of the ground connections.

Coming to the methods of operating protective relays, a very wide divergence of practise is again noticeable. In some cases, one company may have several different arrangements on various parts of this system.

It does not appear that any of the companies have developed an arrangement which meets with its entire approval as in practically all cases where efforts have been made to develop a system of protection, there are either several different arrangements of apparatus in use, or the arrangement that is in use has not been made universal.

The principal points about which the committees inquiry brought out information are as follows:

VALUE OF GROUND RESISTANCE

The value of the ground resistance must be adjusted in accordance with the voltage, generating capacity, number of points at which the system is grounded, system of relays, size of reactors used, electrostatic capacity of lines, and several other features.

In an effort to determine if there was any relation between the voltage of the system and the neutral resistance, a calculation of the volts per ohm, for each system has been made. That is, the potential from line to ground is divided by the value of the neutral resistance. Consequently, the final values obtained are the "volts per ohm" used in proportioning the resistance. This value—"volts per ohm"—is identical with the "maximum ground fault current" which could

exist, assuming that the resistance and reactance of the return circuit, from fault to ground connection was zero, and that the voltage at the fault be held at normal.

In the accompanying tabulation it will be observed that of the thirteen values calculated, eight show a fairly consistent agreement, varying from a minimum value of 908 to a maximum of 2080 and averaging 1500. Of the exceptions, one value, is very much below the average, being 423, and one very much above this average being 3800.

NUMBER OF POINTS AT WHICH IT IS NECESSARY TO GROUND A SYSTEM

It appears to be a well established practise to ground at each generating station. The majority of systems find it advisable to ground only one generator on each section of bus. Naturally, the number of points at which it is found necessary to ground will be dependent on the size and extent of the system and to the transformer connections used at substations.

ARRANGEMENT OF SWITCHES FOR PROTECTING NEUTRAL RESISTANCE AND CONTROLLING GROUND CURRENT

As to this point there seems to be two schemes of operation diametrically opposed to each other. One of these supplies a switch between the generator and ground, this is sometimes automatic and sometimes hand-controlled, but in either event the operation is to break the ground connection. The other places a short-circuiting switch in parallel with the resistance. Both of these arrangements seems to be designed for the protection of the ground resistance grids, rather than for the protection of the system. In general it appears that the main reliance is placed on the operator locating and clearing the feeder in trouble before the resistance is destroyed. While it is evident that the most desirable practise will depend upon the kind of relay protection in use, there still seems to be considerable room for discussion as to which method is preferable, and the operating phenomena and experience gained in connection with each method.

In Table I is found a tabulation of data covering the above points for a number of the most important systems. These data were very generously furnished by the Electrical Apparatus Committee of the National Electric Light Association.

FORMS OF RELAY PROTECTION

There are several forms of relay protection in use and all seem to give more or less satisfactory service, although, as mentioned before, the fact that there does not appear to be even two duplicate arrangements, indicates that the operating engineers have not reached any unanimity of opinion as to the merits of the different arrangements.

The systems of most importance are as follows:

a. Ground relay operated from a sheath type current transformer on each feeder.

VOLTS PER OHM

22	13,200 volts, 60 cycles	Two	One	Resistance between neutral of each machine and ground. Solidly grounded	5 ohms on one generator 0.5 ohms on one generator.			1	
1	13,200 volts, 25 cycles	All	All have neutrals solidly grounded.						

b. Ground relay inserted in the common connection of three current transformers.

c. A similar system operated in connection with a differential relay interconnected with a current transformer in the grounded neutral.

In connection with relaying it is worthy of note that the sheath type transformer is not affected by such triple harmonic currents as may be induced in the common connection of current transformers when a heavy load occurs on the feeder, due to slight difference in the transformers and consequently may be adjusted at a lower setting. It would appear that this point should prove of considerable interest and have a very decided bearing on the selection of the most satisfactory type of relay.

SPECIAL GROUNDING ARRANGEMENTS

Two special arrangements were reported. One was zig-zag connected transformer in series with a three-phase resistance connected to the bus bars as shown in Fig. 2. In the other arrangement the neutral of the system was obtained from the middle point of the transformer primary winding of a 5000 kv-a. bank of transformers; the secondary winding being connected in closed delta. The middle point of the star was connected to ground through a 15-ohm resistance. No load was handled by this transformer bank its sole function being to provide a system ground. See Fig. 3.

FIG. 2—BUS GROUNDING TRANSFORMERS, 6600 VOLTS, 25 CYCLES

ARC SUPPRESSORS

The use of arc suppressors on generated voltage systems does not appear to have any adherents. Apparently, none are, or have been, in service at these voltages. The suppressors have been used at higher voltages but generally have been abandoned even for this service.

REACTORS

The use of reactors is hardly mentioned in any of the replies, however, it is known that many are in use.

As these have considerable effect on the short-circuit current, their influence on the operation of the system and of the protective apparatus should be considered.

NEUTRAL RESISTANCE CONSTRUCTION

The cast iron grid type of resistance mounted on insulators seems to be almost universally adopted, and apparently is giving satisfactory service. The rating of the resistance is usually sufficient to carry the full current to ground for from one-half to two minutes.

FIG. 3

SURGE ABSORBERS

One company operating 29 miles of underground cable at 11,000 volts ungrounded reports the use of surge absorbers for protection of the cable. Although these have not been in operation long enough to give conclusive experience they are reported as satisfactory so far.

The above paragraphs have outlined the present general trend of practice on the various points covered, constituting all companies reporting. However, there is a wide divergency of practice and a thorough discussion of each of the points above presented should prove very valuable. In future reports of the subcommittee it is hoped to offer more detailed information relative to the various methods used and results obtained.

All data obtained from the inquiry sent out by the subcommittee are summarized in Tables IA, IIA and IIIA following.

There is also presented in the appendix a series of excerpts from the various reports received which contain much valuable information supplementing the summarized data.

II—Systems Transmitting at Higher Than Generated Voltage

BY E. C. STONE

Member, A. I. E. E., Chief of Electrical Planning Divisions, Duquesne Light Co.

In this class, thirty-two companies reporting eighty systems with a total generating capacity of 3,984,350 kv-a. responded to the subcommittee's inquiry.

Dead grounding the neutral is clearly the prevailing practise as shown by the following figures:

	No. of Systems	Total Mileage	Average Miles per System
Ungrounded.....	31	5377	176
Dead Grounded.....	39	13,037	334
Grounded through resistance.....	9	2626	285
Grounded through reactance.....	1	100	100

Although the above figures show the trend to be in favor of the dead grounded neutral, the mileage ungrounded is very considerable. The average mileage per system of the ungrounded system is however, less than one half that of the grounded systems. Furthermore a number of the companies reporting ungrounded systems report unsatisfactory operation—generally trouble through high voltage disturbances—and state they are planning to change to grounded neutral operation.

There are several well defined reasons for the prevalence of the dead grounded neutral in this class of systems among which are the following:

a. Higher transmission voltages where a dead ground stabilizes operating conditions and simplifies the insulation problem.

b. Lower maximum currents to ground both on account of the higher reactance in all parts of the system, especially the step-up transformer and of small generating capacities on the average.

c. Greater use of outdoor installations at the higher voltages where line damage is possible from heavy ground currents.

The limitations to the dead grounded neutral is of course the maximum short circuit developed in case of a grounded phase and the damage which may result therefrom.

On systems with dead grounded neutral the usual practise is to ground at fairly frequent intervals; the average number of miles per ground on 34 such systems is 32 as against 136 miles per ground on 9 systems with neutral grounded through resistance.

On long transmissions at high voltage both transmitting and receiving ends are almost invariably grounded, while in high or medium voltage networks the neutrals of the transformer banks are frequently grounded; not only at generating stations but also at all or nearly all step-down systems. This practise is undoubtedly due in part to the simplicity of making dead ground connections. One company reported very frequent grounding on account of soil conditions which makes the conductivity of the individual grounds uncertain.

The only company in this class reporting over one hundred miles of cable reports on three hundred and fifty nine miles at 24,000 volts. The neutrals of the step-up transformers are dead grounded at two generating plants. Automatic switching is prevalent on

this system and is operated in a network the same as similar lower voltage systems. Above 30,000 volts, only one company reported operation of cable. This system consists of 28 miles at 33,000 volts constituting two tie lines between principal power plants; each line is supplied with its own step-up and step-down transformers. The high-voltage windings on both being connected in star with neutrals dead grounding. Switching is done on the low-tension side.

Most of the systems in this class operating with resistance in the neutral are of comparatively recent development. The magnitude of resistance used shows wide variation. The prevailing type of resistance is the cast iron grid similar to that used in generating stations, described in the first section of this report.

Two systems, however, are using water rheostats with apparently entirely satisfactory results.

Dominating influences leading to the insertion of resistance in the grounding neutral of high-voltage systems are the rapidly increasing generating capacities of these systems, leading to dangerous currents with dead ground and increasingly rigid demands for high grade service, requiring the elimination of voltage disturbances which would result from heavy ground currents. Conditions making such operation practicable are the high reliability of insulators; development of automatic circuit breakers for heavy duty, at high voltages and improvement in relay systems which make selective relaying possible on ground current of less than full load of the lines protected.

One company reports the use of a Petersen Coil on a 44,000-volt system of one hundred miles extent, all overhead. The installation is a recent one and no comments were made as to the results attained.

Two companies reported former use of the arc suppressor. Both however, regarded this equipment as outgrown and expressed themselves in favor of automatic circuit breakers and selective relays rather than the arc suppressor as protective equipment.

III—PROTECTION OF HIGH-VOLTAGE UNDERGROUND CABLES

While seven companies reported operating 525 miles of cable above 20,000 volts only one of these reported cable operating above 30,000. The subcommittee has, however, also secured data on four British installations of cable which are now in operation at 33,000 volts. The following is a summary of the protective arrangements used on the one American installation and on the four British installations which were reported on:

It will be noted that four out of five systems have neutral dead grounded and operate each cable as a separate unit isolated at both ends by transformers. Only one company attempts anything like a transmission net work with sectionalizing switches.

Inquiry among cable designers which has been made by the subcommittee brings out a definite and uniform opinion that in the present state of the art, cables

No. of company	Number of lines	Miles each line	Arrangement of neutral	Lightning arresters	Switching		Scheme of operation
					Location	Method	
6	2	14-1/2	Dead grounded on both lines at both ends	None	Low-tension side	Automatic	Separate step-up and step-down transformers for each cable at both ends
38	1	15-1/2	Dead grounded generating end only	None	Same	Same	Same
39	2	9	Same	None	Same	Same	All operated through one 33-kv. bus
40	$\begin{Bmatrix} 2 \\ 1 \end{Bmatrix}$	$\begin{Bmatrix} 2-3/4 \\ 9 \end{Bmatrix}$	Grounded at step-up transformers through resistance 200 amperes 2 min.	None	High-tension side	Same	
41	1	4-1/2	Dead grounded generator end only	None	Low-tension side	Same	Separate step-up and step-down transformers at both ends

operated at 33,000 volts or above should have the neutral dead grounded at as many points as possible.

With reference to switching practise, the high-voltage, high duty switches now available should prove entirely adequate for switching on both routine and automatic on failure on high-voltage cables. If such cables are to be used to any great extent in future transmission systems the present practise of isolated operation must necessarily give way to operation in net works,—in many cases connected with overhead lines—with the usual automatic sectionalized switches.

Even if greater voltage disturbances are produced by switching at cable voltage rather than on the low-tension side—and opinion is more or less divided on this point—such operation cannot be avoided.

One manufacturer writes as follows with reference to these matters:

“Testing and research have indicated that the low-tension switching generally produces less voltage disturbance than high-tension switching. However, the voltages produced by switching are only a part of the disturbances to which cables are subject. If low-tension switching is used, therefore, there will be a slight probability of fewer troubles in the cable, and where individual transformer banks are used for the cables it is easy to use low-tension switching. There will be many places, however, where it is necessary to use a high-tension bus and high-tension switching. We believe this will be the case in the future and that the system should be made in some way proof against the disturbances resulting from high-tension switching. Future experience will indicate whether this can be done best by increasing the insulation of the cable or by installing protective devices, such as resistance in shunt with reactance or resistance in series with condensers.

While cables are less subject to lightning disturbances than overhead lines, yet, it appears desirable to protect such cables by lightning arresters whether they are connected to overhead lines or not. Since the cost of arresters is low compared to that of the cable, that is, the insurance is cheap, they should without doubt be protected by lightning arresters where they are connected with overhead lines.”

IV—Conclusions and Summary

BY E. C. STONE

Duquesne Light Company, Chairman of Sub-Committee

From general considerations fundamental to the problem and analysis of all data received by the Sub-committee, the following conclusions are reached:

OPERATION WITH UNGROUNDED NEUTRAL

The only argument in favor of operating a system with ungrounded neutral is the possibility of continuing in operation with one phase grounded. In the early days of power transmission, when mileages were small and voltages low, this was possible not infrequently, and on systems in undeveloped territory, especially with lines running radially out from a central power station, such operation became of distinct economic advantage. However, as the size of these systems increased it was soon found that in a majority of cases that the increased charging currents on a grounding phase not only made continued operation impossible but developed excessive voltages at other points of the system which resulted in one or more break downs, thus causing serious interruptions to considerable portions of the system as well as material damage to valuable equipment.

WHEN TO GROUND THE NEUTRAL

The grounded neutral of a transmission system performs two definite functions:

a. It acts as an anchor to hold the generator windings, transformer windings and line wires at potentials to ground which are within the values for which a system is designed;

b. It completes, in case of a grounded phase, a closed circuit through the generator which short circuits the electrostatic capacitance, of a system to ground and prevents the building up of arcing grounds involving disastrous voltages.

The dead grounded neutral limits the voltage stresses that may occur at normal frequency to a value of approximately 50 per cent of that which may occur with any other operating arrangement.

The creation of excessive voltages in transmission systems, both from internal surges and arcing grounds depends largely upon the amount of energy storage in the electrostatic capacity of a system which increases

directly as the number of miles of line and as the square of the voltage. Hence the increasing mileage and increasing voltage of transmission systems have been the definite factors leading to grounding of the neutral.

These conclusions have been amply proved by operating experiences. In many cases the excessive voltages have become increasingly frequent and disastrous as ungrounded neutral systems have grown and have subsequently been practically eliminated by the grounding of the system neutral.

From the data available it is not possible to indicate, except in a very general way, at just what stage in the growth of a system the neutral should be grounded. When however, the magnitude of any system has become so great that evidences of excessive voltages become frequent and insulation failures develop simultaneously on different parts of the system, it is time to consider grounding of the neutral.

In this connection, it should be remembered, that because of the higher electrostatic capacity of cables, one mile of cable is equivalent to approximately 25 miles of overhead lines. On all systems reporting only 6385 miles out of a total of 31,408 are operating with free neutral. Mileage of systems is the determining factor in grounding and is shown by the fact that the average mileage per ungrounded system is 152 against a mileage per system with dead grounds of 441 and with resistance grounds of 248. The latter being chiefly on systems consisting largely of underground cable.

HOW TO GROUND

Four factors must be considered when designing a neutral ground for transmission systems:

- Excessive voltages must be taken care of.
- Excessive currents must be prevented.
- Due consideration must be given to conditions imposed by selective relaying.
- Due consideration must be given to reducing to a minimum the effect of system disturbances on interference with operation of motors and other load.

As previously stated operating experiences show conclusively that dangerous voltage disturbances will become more and more prevalent as *mileage* and *voltage* of systems increase, unless suitable grounding of the neutral is resorted to.

Several companies grounding through a resistance report gradual reduction of resistance as the magnitude of the system increases. With this premise, let it be assumed that for the same degree of protection on various systems, the grounding resistance should vary inversely as the total system charging current. Inductance and electrostatic capacity per mile of overhead line and cable do not vary very widely within the ranges of construction used by the systems under consideration; let them be assumed constant with the electrostatic capacity of cable taken as 25 times that

of overhead line. Expressed as a formula these assumptions give the following results:

$$(L a + 5 + 25 L b) \times f \times R = K.$$

where:

$L a$ = Miles of overhead line

$L b$ = Miles of cable

f = Frequency of system in cycles per second

R = Resistance of combined neutral ground circuit, in ohms.

A calculation of the value of K for those systems on which sufficient information is available shows interesting results. If K came out a constant for all systems it would mean that a definite relation had been established between systems charging current and ohmic value of grounding resistance. As a matter of fact however very wide variation is shown as indicated in the following summary:

	No. of Systems	Value of $K/10^6$		
		Minimum	Average	Maximum
Transmitting at generated voltage.....	8	0.008	1.04	3.55
Transmitting at higher than generated voltage.	7	0.022	0.52	2.00

Petersen, inventor of the Petersen grounding coil, has given a value of K of 6.2×10^6 as suitable for calculating a grounding resistance of proper ohmic value for preventing the accumulative voltage variations from arcing grounds. This would give a value of resistance from 6 to 12 times the average, as shown by the above data, and two or three times the maximum values in actual use.

In view of the fact that some of the later grounded neutral installations have been installed with the highest resistance values it is of interest that one company with a relatively very high grounding resistance reports occasional insulation failures simultaneously at different points on the system, similar to those which previously occurred on the ungrounded system.

So much for the higher limit of resistance value. The lower limit is determined by the maximum permissible current flow in case of a grounded phase and this in turn is determined by the possible damage to equipment and disturbance to service, resulting from such current flow. The limits have however, a considerable range depending on service conditions, system connections, outdoor and indoor bus structures, etc.

The data collected show that of the 49 systems with grounded neutral transmitting at higher than generated voltage and operating 24,926 miles of line 39 systems with 18,478 miles are dead grounded, while only 9 systems with 2626 miles are grounded through resistance.

The reason for the predominance of the dead grounded neutral on the higher voltage systems seems clear when it is remembered that the reactance of a

system goes up at least in proportion to the voltage, with the result that relatively small currents flow in case of a grounded phase at the higher voltages. For example—assume that a 200,000-kv-a. station is designed for 11,000-volt operation and that the generators have 6 per cent internal reactance, the maximum current which could then flow to ground if neutral of all generators were dead grounded would be:

$$\frac{200,000 \times 1.73}{11,000 \times 0.06} = 525,000 \text{ amperes}$$

If however, the generators step up their entire output to 132,000 volts through transformers of 6 per cent reactance and all transformer neutrals are dead grounded, the maximum possible current at the high-tension bus would be reduced to one twenty-fourth of the above value or 20,000 amperes.

From another point of view if it was found that 25,000 kv-a. was the maximum permissible station capacity at 11,000 volts for dead grounded neutral, then a 600,000-kv-a. station at 132,000 volts might have its neutral dead grounded without any increase in maximum possible ground currents. The resistance of a ground circuit through a fault is so low that it is practically negligible compared to the impedance of the rest of the circuit. Hence the greatest currents arising from grounding the neutral may occur at the large stations at the lower voltages and it is at these stations that limitation of ground current by insertion of resistance in the neutral becomes compulsory.

From the point of view of relay operation, the dead grounded neutral is the most satisfactory arrangement, since it allows ample currents for positive selective action of relays and permits using the same relays for protection against grounds and short circuits. A low internal resistance of the order of two or three ohms does not materially alter this condition, since ground currents will be still much in excess of normal full-load line currents. The information received indicates that selective relay requirements, have been a limiting influence in 12 cases on the maximum value of resistance used in neutral grounds. See Tables 6A and 6B.

On the other hand, the demands of a rapidly growing motor load—much of it synchronous—for relief from inconvenient disturbance due to drop of voltage has created a tendency toward the use of greater values of ground resistance particularly on high-voltage overhead systems where most break downs are grounds, rather than short circuits, and individual lines have very large carrying capacities so that a single fault to ground may effect a very large block of service.

In the last few years there has been a fairly marked trend toward the use of higher resistance in grounded neutrals especially in the higher voltage systems. This has led to the development of a number of relay schemes in which selective operation of breakers is obtained with ground currents less than the full-load

current of the line. Six companies are using schemes of this nature on parts of their system.

In studying the effects of heavy ground currents on the operation of synchronous machinery a series of tests was made by one of the manufacturers under conditions approximating those of a certain transmission system. The results of this test indicated that the average voltage at the motor could not drop more than 30 per cent without interference with operation. With greater drop in voltage than this motor generators may be expected to drop out of step and rotaries to flash badly. The average drop of thirty per cent at the load, means of course, materially less than this on transmission systems since when the voltage begins to drop, motors immediately draw more current, thus adding to the drop due to ground currents.

Insertion of resistance in the neutral reduces the distortion to the voltage triangle in case of ground, as well as the average drop in voltage.

Calculations of the maximum current which will flow in case of a grounded phase on systems with neutral grounded through resistance have been made by dividing the rated system voltage, from neutral to phase wire, by the resistance, at the grounding point, assumed to be in parallel. On 17 systems for which this information is available the following figures for maximum ground current have been obtained:

Maximum	Average	Minimum
5950 Amperes	2080 Amperes	102 Amperes

Under 700 amperes, 5 systems: 1100 to 2600 amperes, 8 systems: 4000 amperes or over, 4 systems.

TYPE OF RESISTANCE

Details of the data obtained by the Subcommittee will be found in Tables 3A, 3B, 6A and 6B. Prevailing practise calls for grounding resistances made up of cast iron grids for either indoor or outdoor operation.

These grids are designed for a maximum temperature of 350 deg. cent. to 600 deg. cent. The average being about 400 deg. cent. On 30 grids now in service, the time required to reach this temperature runs from 10 seconds to two minutes with an average of 45 seconds. One grid has a time rating of 10 minutes having replaced a 30-second grid on account of burning out of the latter.

In general, these grids are giving satisfactory service. Of 11 systems for which information was furnished on this point, 8 reported no trouble, while 3 using thirty second resistances and one having a 10 second resistance reported trouble from burnouts on sustained grounds. Of two of these using 30 second grids, one has gone to dead grounding and the other to 10 minute rating, while the company using the 10 second resistance on a 66-kv. system has installed a circuit breaker to automatically short-circuit the grids on maximum ground current sustained for 10 seconds.

Two companies are using water rheostats for ground-

ing resistance, the ohmic values are five to one hundred and fifty ohms. One of these reported satisfactory operation and one burnout due to low capacity. One company reports resistance of 60 to 100 ohms made of

absolutely prevented by this device which is called the Petersen coil, after its inventor.

Although a number of his schemes of grounding through reactance have been in operation for some time in Europe, only one company in the United States was reported to the subcommittee to be using it. A thorough analysis of the theory of the grounding reactance was presented by Messrs. Conwell and Evans in the A. I. E. E. JOURNAL for February, 1922, and a report on practical results obtained from operation of such a coil over a period of eighteen months is presented by Messrs. Oliver and Eberhardt coincidentally with this report.

Grounding the neutral of a transmission system in a suitable manner is thoroughly standardized in the United States as the best protective measure against internal voltage disturbances. This conclusion is definitely proved by the data received by the subcommittee.

PROTECTIVE SCHEMES OTHER THAN GROUNDED NEUTRAL

Several companies have used various forms of arc suppressors with more or less success, for a number of years. Outlines of their experiences will be found in the "excerpts" in the appendix of this report.

In general the arc suppressor has proved only reasonably successful as it has many limitations. The consensus of opinion seems to be that with the high duty circuit breakers and selective relaying now available the arc suppressor should be abandoned. One company reports the use of surge absorbers on their ungrounded cable systems with satisfactory results. This device consists of reactance and capacitance in series in the form of a static condenser and this connected into the line in a manner similar to lightning arresters. The use of this device is suggested in addition to the dead grounded neutral for protection of very high-voltage cables.

In Europe it appears that considerable success in protecting against excessive voltages has been obtained by the use of horn gaps in series with the resistance connected to the line, the same as lightning arresters.

One case has come to the attention of the subcommittee where the neutral of a transformer bank was connected through a spark gap to ground.

In conclusion the present situation as to grounding the neutral of transmission systems is summarized in the following paragraphs:

1. Grounding the neutral has proved successful to a very high degree in limiting trouble from excessive voltage on transmission systems. Case after case is on record where frequent and destructive insulation break downs on systems operating ungrounded have been practically eliminated after the neutral is grounded.

2. The trend of present practise is definitely toward grounding the neutral of large transmission systems.

FIG. 4—GROUNDING OF 13,200-VOLT, 60-CYCLE SYSTEM

Monel metal, the ratings being 67 amperes for 10 seconds and 40 amperes for 20 seconds respectively.

GROUNDING THROUGH REACTANCE

The most recent development in methods of grounding of neutrals is the use of a reactance instead of

FIG. 5—SHOWING METHOD OF GROUNDING AND PROTECTING 15,000-VOLT, 25-CYCLE STATION TIE

resistance. If for any given system, the reactance is properly proportioned it will exactly neutralize the capacitance of the transmission system to ground, so that in case of a grounded phase no current will flow through the fault. It is claimed that arcing grounds are

Increasing mileage and voltage have been the factors necessitating this practise:

- a. On systems transmitting at generated voltage, the neutral usually is grounded at each generating station with resistance of low value.
- b. On systems transmitting at higher than generated voltage the neutrals of the transformers are grounded

FIG. 6—6600 AND 11,000-VOLT RADIAL FEEDER RELAYS, 25 CYCLES

at each generating station and some or all substations.

- c. Where resistances are used they are generally made up of cast iron grids with time ratings at maximum current of 30 seconds to 60 seconds.

3. The use of arc suppressors has been very generally abandoned. This is not because such apparatus was without merit since some fairly good results were

FIG. 7

These two plants are operated in parallel.

obtained with its use, but rather because of the development of high interrupting capacity breakers and selective relays which are found to be a better solution to the problem.

4. Certain departures from present standard practise in neutral grounding as outlined above are taking

place which are apparently proving successful and are likely to become increasingly used:

- a. High resistances in the neutral ground connection of the order of one to one and one half ohms per thousand line volts. One company is using a resistance of 150 ohms on a 26,400-volt system.
- b. Reactance, (Petersen coil), is being tried instead of resistance in the neutral ground connection.

EXCERPTS FROM REPLIES TO INQUIRY

The following excerpts, which are taken from the replies submitted in answer to the questionnaire, give in a general way the attitude of the various operating engineers towards this subject. These replies refer to the systems as a whole and include lines operated both at generated and transformed voltages, and, consequently, refer to methods of grounding the neutrals on the high-tension side of transformer banks as well as the generator neutrals.

The company number at beginning of each excerpt furnishes a reference to other data on same company in the tables.

COMPANY NO. 1

(1-A). The method of grounding is considered entirely satisfactory. The only difficulty which has been experienced is the burning up of the cast iron rheostat in case the ground, due to failure of some other protective equipment, should hang on too long.

When the main power house started in operation the neutral of one of the transformers connected to each of the two high-tension circuits was connected directly to ground without any resistance. As the summer of 1911 proved that these lines were subject to considerable lightning trouble it was tried for a while to run the system ungrounded, but as this did not minimize the effects from lightning this method of operation was quickly abandoned again in favor of the grounded system which permitted selective relay operation by means of neutral relays in the ground connections. Resistances between the neutral points of the transformers and the ground were shortly after introduced because it was believed that some of the transformer breakdowns experienced during 1911 might have been due to excessive flow of current which would occur through the dead grounded transformer when only one of a number of transformers in parallel was grounded. Resistances made of concrete separating electrodes of wire netting were first tried but proved entirely unsuitable as they would cause arcing when heavy current passed through them and were abandoned in favor of the present cast iron grid rheostats.

Arc suppressors and a field destroying device have been used a number of years on the transmission system with fair success. Both have been abandoned, however, due to the fact that they were found unnecessary, as four parallel circuits have been constructed and an elaborate relay system of overload and neutral relays at the generating station and reverse power relays

at the terminal station have been brought to such perfection that the other devices were found unnecessary on the system.

(1-B). We originally operated without neutral grounded. About 1907 we grounded the neutral of one generator through a grid resistance having 10 ohms. The object of this grounding was to reduce voltage strains on the system. As the capacity of our system increased it became necessary to reduce the resistance of the grounding resistance to accomplish the same results. About 1915 we burned up the grounding resistance and as we were approaching zero resistance we decided to abandon the resistance. Since that time we have operated with the neutral solidly grounded and have found this practise satisfactory.

COMPANY 5

We originally installed resistance in series with the neutral but it was abandoned, and since we have been operating with a dead-ground we had an arc suppressor a number of years ago, but it did not seem to be of any particular service.

COMPANY 7

The operating condition during the period from February to August was such, however, that for all practical electrical considerations the system was operated as a purely grounded system. On ungrounded operation, from the beginning of March to the end of August 1920, 61 cases of trouble interfered with the operation of the system. Upon investigation it was found that there were actually 120 cases of trouble; that is, usually each case of trouble brought with it a reflected case of trouble; *i. e.* interference with operation was usually caused by more than one simultaneous breakdown. We have record of five cases of breakdown occurring simultaneously and as can be readily imagined it was somewhat difficult, if not impossible to actually establish which was the primary cause. Against the before-mentioned our operating experience for the same period in 1921 with dead grounded neutral showed that there were 47 cases of operating interference and but 48 cases of trouble found. This means that when a breakdown occurred on the grounded star-connected system it stayed as an individual case and did not bring with it a multiplicity of simultaneous breakdowns.

COMPANY 9

Full load on our feeders is from 200 to 250 amperes. The relays are adjusted to trip on approximately 120 amperes ground current.

COMPANY 11

Before grounding neutral, simultaneous cable failures did occur and in one case five faults appeared. Since grounding neutral only one has occurred when two feeders failed at once.

COMPANY 18

The 150-ohm resistances in the two 26,400-volt sections have not been in service long enough to supply sufficient data regarding the suitability of this value of resistance. The ungrounded sections are not entirely satisfactory in comparison with grounded operation.

COMPANY 20

On four occasions the 1000-ampere, 30-second resistor through which the neutral bus of the 60-cycle, 13,200-volt system was grounded failed in service because of sustained grounds on other station busses with the ground current divided over several feeders. In each case the resistor burned apart leaving the neutral bus ungrounded.

A new resistor rated at 8 ohms, 100 amperes for 10 minutes has been installed. A thermal relay with current time characteristics similar to those of the resistor opens an oil circuit breaker in series with the resistor when the grids reach a dangerous temperature.

COMPANY 21

Our system was first changed from free neutral to solid grounded neutral. This eliminated the trouble due to surges but caused our lead cable sheaths to be burned when the line became grounded. To remedy this, we changed from solid grounded neutral to neutral grounded through resistance. After trying various values of resistance, we have found that approximately 5 to 10 ohms gives very satisfactory results on our systems.

COMPANY 24

No trouble has been experienced with the resistance used in grounding the neutral of our transmission system, while in service. Inspection of the grids has shown broken grids at various times. However, as the units are built up with two grids in parallel, this at no time has opened up the circuit to ground.

COMPANY 29

As our 11-kv. system has increased in extent and consequently in electrostatic capacity, surges due to arcing grounds have become increasingly violent. They are particularly destructive to lightning arresters, cable terminals, transformers etc., we therefore propose when one new 15,000-kw. 11-kv. turbo generator is installed to ground the neutral of the system, but whether through resistance or not has not yet been determined.

COMPANY 36

The 60-cycle system was originally operated with a free neutral but after failure of the insulation of a large generator, cause of which was attributed to voltage disturbances which would very likely not have occurred had there been a neutral ground connection, plans were made for connecting this neutral to ground through an 8-ohm resistor.

Experience obtained during the next few years indicated that there was a certain number of faults to ground through which the current was not of sufficient value to cause the circuit breakers to open, and it, therefore, appeared advisable to reduce the resistance with the ground connection. This was done in such a manner as to obtain a resistor of 4-ohm resistance designed to carry 2000 amperes for one minute.

At the present time there is a number of trial installations of low-current ground relays connected in the common return wire of the current transformer secondaries which operate alarms to indicate to the operator which line is grounded. Owing to the fact that nearly all transmission is through underground cables, the ground faults usually develop into short circuits before the operator can clear the line manually. It is possible that in the future installations will be made of ground relay protective equipments which will automatically insolate a grounded section.

COMPANY 10

At the time the plant was built, the manufacturers did not feel capable of building 110,000-volt oil switches which could be relied on to open short circuits safely with the power of the plant behind them. Instead, therefore, of relieving short circuits which might occur on the 110,000-volt lines by automatically opening the supply with oil switches, all of these oil switches were made non-automatic and provision made for lowering the voltage on the line in trouble by cutting in resistance of the exciter fields. After the arc was extinguished in this manner the voltage was again brought up on the units and service re-established.

You will see that the above method of operation meant that every time a short circuit occurred on the circuits service was interrupted. We therefore looked around for some suitable way of taking care of such service interruptions and installed the arc suppressor for that purpose.

The arc suppressor has very satisfactorily performed the work for which it was intended and has taken care of about 80 per cent of the line flashovers, which are practically all caused by lightning, without the loss of load. On the other hand, severe short circuits at receiving end caused by cable failures, etc., also operate the arc suppressor and under such conditions the load is generally shaken off, so you will see that there are times when we would be better off without the arc suppressor.

In addition to the above, there is no doubt in my mind but what the short circuits which the arc suppressor places across the lines at the power house is very severe on the transformers and while we have had no failures of such apparatus, it has never seemed to me

just right to place such severe short circuits on the generating equipment if it could be avoided.

The state of the art at present is such that I believe if we were building a new plant at the present time, all of the outgoing lines would be equipped with suitable oil switches which would be made automatic and short circuits would be taken care of by promptly opening the circuit in trouble. For this reason I believe our arc suppressor equipment is out of date and I doubt very much whether a story of the operation of the arc suppressor would be of very much value, except as a matter of history.

Discussion

**GENERAL CONSIDERATIONS IN GROUNDING THE NEUTRAL OF POWER SYSTEMS (DEWEY);
THE NEUTRAL GROUNDING REACTOR (LEWIS)
OPERATING PERFORMANCE OF A PETERSEN EARTH COIL (OLIVER AND EBERHARDT);
PRESENT DAY PRACTISE IN GROUNDING TRANSMISSION SYSTEMS (COMMITTEE REPORTS; (a) SYSTEMS TRANSMITTING AT GENERATED VOLTAGE, (WOODRUFF); (b) SYSTEMS TRANSMITTING AT HIGHER THAN GENERATED VOLTAGE (STONE),**

PITTSBURGH, PA., April 24, 1923.

R. W. Atkinson: I want to say a word with regard to the comparison between the condition of a cable system and an overhead open-wire system with regard to the grounding of the neutral. There is a large and important difference for two reasons. The most important reason is the relative cost of insulation of the cable system as compared with the overhead cable for high voltage. The insulation is a very important part of the transmission system, whereas it is a relatively minor part in the overhead system. You can afford in the overhead system to put on insulation to take care of the voltage rise due to abnormal conditions, and you can afford to put on the insulation to take care of service conditions; whereas the same difference in service conditions costs you a whole lot more in insulation of cable systems. Another

difference from the standpoint of operation, is the very much greater electrostatic capacity for the cable system.

Another thing that we have often overlooked, not only the operating people but some of engineers connected with the manufacturers, is that when you have the same thickness of insulation between conductor and sheath in a cable, as you have between conductors, you really haven't the same voltage strength.

The best reason perhaps is the fact that the ratio between the maximum stress and the average stress is much higher where you have the stress concentrated only on one side, as you do from the conductor to the sheath, as compared with where you have it concentrated in two places, and your stress subdivided. Your belt insulation is probably not equal in its voltage resisting strength to the insulation on the conductor, and as a general proposition a cable with equal insulation between copper and sheath as between conductor and conductor; has very much less actual strength from copper to sheath than from copper to copper. Therefore, if we only got the same amount of voltage disturbance or the same potential between copper and lead, as between copper and copper, we would be expecting more trouble.

As a matter of fact, with the underground system, it has been shown to proceed to higher ground as in cases of arcing grounds. Coming to the other side of the case, the neutral grounded through resistance; there we have removed the most serious source of possible disturbance, but we still have the condition that any conductor of the system may be subjected suddenly to a potential, exceeding line potential. In view of the less apparent strength of the insulation from conductor to sheath, we want to have more insulation there than we would have applied otherwise.

Another point to consider in comparing systems is the matter of the size of the system. A very few cable systems operate without grounded neutrals at voltages above 90 kv. and a few have operated with resistance in the neutral. I believe all of those systems above 20 kw. which have not operated with solidly grounded neutral are very small or the actual part of the system itself is small. That is, if we have a bus at the generator voltage and a step-up transformer to the cable, and then through the cable to another transformer, without going to a bus, then only the one cable is involved. That system is radically different in its operating condition from the other system, whereby the voltage is stepped up before you get to the bus, and you have a bus voltage above generator voltage. Now, in that case, all of the cable on the system is subjected to the abnormal condition resulting from a single voltage failure, which means that we have the difference between the large and small system.

The large transmission system may have a number of small units each having the same characteristic, as far as the effect on grounding neutral is concerned, as a small transmission system, and the effect is this.

A system, of course, without grounded neutral acts just exactly like one with the grounded neutral as long as nothing happens. As soon as something happens, you put strains on the system, and one thing causes something else, and that causes something else again, and troubles will be multiplied in proportion to the square of the amount of cable involved, perhaps, if they are troubles due to incomplete grounding.

There is another thirty-three thousand volt cable in operation in this country, (it is a very small amount in addition to the one which is mentioned here) in Los Angeles, and that is operating with a solidly grounded neutral system, and has been for nearly two years.

F. C. Hanker: Mr. Dewey has given us a very comprehensive review of the problems involved in grounding the neutral of transmission and distribution systems. I do not believe that too much emphasis can be placed on the advantages of operating a system with the neutral stabilizer. The principal argument for the free neutral, that it permits continuity of supply

even when one phase is grounded, is misleading in that it is a dangerous practise as well. The possibility of arcing grounds with their resultant recurring oscillations are so likely to cause extremely high voltages as to be dangerous. It is far better policy to remove a circuit that has failed from service rather than risk more general and widespread breakdowns due to high-voltage disturbances.

While it is true that the smaller systems can generally operate successfully with the neutral free, it is also true that is a limit to the growth of a system. One of the systems referred to by Mr. Dewey, the Montana Power Co., was initially a delta system operating with the neutral free. As the system grew the effect of failures became more serious and widespread with the result that the engineers practically reached the conclusion that there was a definite limit to the size of a transmission system that could be operated successfully. The solution of the problem was in the stabilization of the neutral. This has proved so successful that, based on the experience of several years operation, the present conclusion is that there is no limit to the size of a transmission system.

The strongest advocates of the stabilized neutral are the Pacific Coast systems. In 1898 a transmission system operating at 60,000 volts was planned by the Standard Elec. Company. They adopted the 60-cycle, grounded system and the same plan was adopted later by the Bay Counties Power Company. The grounded system has been generally used on the Pacific Coast from the beginning and engineers, prominent on the coast have expressed the opinion that their success is largely due to the fact that the neutral was fixed.

An analysis of the relative magnitude of possible surge voltages on the free neutral and grounded neutral systems will show to the advantage of the grounded system. Advantages of this feature can be considered in two ways, first by retaining the greater factor of safety, in insulation strength and second, by grading the insulation. On lower potentials up to 110,000 volts the advantage in cost is not great and it may be desirable to retain the higher factor of safety. On higher voltage systems the saving is appreciable and we are justified in taking advantage of the reduction. Very appreciable savings have resulted in apparatus purchased for operation on 220 kv. and have been accepted by operating engineers after careful comparative analysis of various factors affecting the conditions.

J. B. Taylor: A few years ago there would have been little difficulty in securing a number of papers on this general topic in which perhaps the majority would have favored working without grounded neutral. The absence of any paper today in which the author definitely advocates running in the old method is quite obvious; it is not necessary to comment on it. The practise is fairly well crystallized and those who haven't swung into line, as far as I can discover, are holding back either for reasons of expense or because their systems may be in such good shape that their troubles with the free neutral are not serious.

Of course, if there were no causes of trouble, there would be no point in deciding whether to work one way or the other, and the whole question could be left open. Consequently, it isn't possible for me at any rate to dispute much of what is said here, and a discussion is necessarily limited to commenting and questioning a few of the points which boil down really to comparatively minor differences in practise.

We might emphasize this best by calling your attention to the fact that Mr. Dewey in his conclusions advocates grounding heavily so that voltage rises will be kept down at the expense of currents. Mr. Lewis, in his conclusions, says the Petersen coil is a good thing where it is desirable to keep down the rises in current at the expense of voltage. In the report of the committee, I think you will find on one page a statement that the tendency is to cut out the resistance and elsewhere a statement that the tendency is to increase the resistance.

Now, this state of affairs is not disturbing; all systems are

not alike. They operate at different voltages, have different lengths of line; the cables are from different makers and loaded to different extents. The ducts are laid differently, so that there are plenty of good reasons why the prevailing kind of trouble which one system has is different from the prevailing kind of trouble which another system has.

One thing to which the engineers who have presented the papers, at any rate, agree and probably a great many more, is that grounding in some form is desirable.

Now, the particular form seems to come down to a matter of accumulated experience on the particular system and engineering judgment on how to meet that particular condition.

I am inclined to think that if you can clear your faulty cable without a big rush of current, even though your apparatus will stand that rush, there is particular virtue in doing it that way. Consequently, continued experience in designing selective relays and these various differential arrangements will perhaps be the tendency.

I am also inclined to make a general comment on some of the statements in the committee reports. It seems to me there is a little confusion in spots between presenting the present practise and stating the trend.

Now, a census does not always show the trend of things at all. It may show the amount of previous mistakes compiled, so we must discover the trend in more subtle ways instead of counting up what you already have on your hands. I would draw a line through the word trend, because it appears to have been put in where they should have said the practise is thus and so.

There is only one more point. In the committee's reports where there is a discussion of what determines the value of resistance in the neutral, where resistance is used, on the third page, the middle of the first column. My comment is that the most important controlling factor in determining this resistance is included under the several other features not mentioned. The current-carrying capacities of the cable determines the setting of the oil switch, very often set on triple, double and normal load.

The neutral resistance, to work properly, must take into account the setting of the switches. I believe that this has been the controlling factor in determining the value of this resistance.

L. P. Ferris: In presenting these remarks I want to emphasize that I do not wish to suggest that the features which I will mention are necessarily to be considered controlling. All I wish to do is to call attention to some of the effects which manifest themselves and that these effects should be given their due consideration and nothing more.

On the third page of his paper Mr. Dewey states as a conclusion, that no serious telephone interference under normal operating conditions need be anticipated even though the neutral is grounded at many points. I believe that operating experience does not justify such a generalization, although there are doubtless instances where this conclusion holds. There is just this difference, under normal operating conditions, between the grounded neutral system and the isolated neutral system: In the former you give opportunity for triple harmonic voltages to be impressed upon the line with respect to the ground, and thereby affect the neighboring communication circuits, whereas in the isolated systems these triple harmonic voltages and currents cannot get out on the line. There are certain minor exceptions to that which we won't go into.

Sometimes this effect is emphasized by multiple grounding of the neutral although you can create a disturbance with only a single ground. The capacity of the system to ground presents a path for any triple harmonic current, the circuit being completed via the neutral. Such current would in general be negligible from the standpoint of the operation of the power system, however, there are cases where it is important in its effect on neighboring circuits.

I am glad to note on page 5 of Mr. Dewey's paper his con-

clusion that the use of Y-Y transformers is very limited in view of the interference which they tend to cause in the neighboring communication lines.

Obviously from the standpoint of telephone interference it is an advantage to limit the short-circuit current to ground which if not limited may give severe acoustic shocks to operators listening on parallel circuits. Mr. Dewey, evidently inadvertently, stated the contrary at the bottom of his fifth page.

Will Mr. Dewey please explain what is meant by a semblance of arcing ground effects.

At the midwinter convention of a year ago, I called attention to some of the properties of the Petersen coil from the standpoint of its effects on induction into neighboring circuits. It is very gratifying to note from the paper by Messrs Oliver and Eberhardt that operating experience with this device shows that its use reduces the interruptions due to flash-overs from lightning by some 83 per cent. Without that device, it is fair to conclude that in those cases in which the coil cleared the fault there would otherwise, in general, have been a direct short circuit to ground on the system, and had there been a telephone line from Lock 12 extending toward Vida, it is reasonable to expect that in a good many of those cases there would have been induced in the telephone circuits high voltages, some producing acoustic shock. In such a situation the use of this coil would have saved about 83 per cent of the disturbances in the neighboring circuits.

This installation uses in combination with the Petersen coil a short-circuiting switch which solidly grounds the system in those cases where the Petersen cannot be expected to clear the line. In this instance there is no particular reason why a resistance would offer advantages over the direct grounding of the system. However, had there been a telephone system exposed to this power line, in those cases where it was necessary to resort to other means than the Petersen coil to clear the line, if instead of grounding the neutral solidly the switch had connected the neutral to ground through a moderate resistance of such value as to permit reliable operation of a ground relay you could have accomplished the desired result and at the same time prevented a condition which might give rise to a disturbance in the telephone system. The combination of this coil and a moderate resistance, may, therefore, offer advantages in situations where we have disturbances in telephone lines to contend with.

In closing, I would make one suggestion for the consideration of the authors of the Petersen coil papers. The network of the Alabama Power Company with which the coil is associated is in the form of a Y, and Mr. Lewis presents curves which show that at resonance the current in the neutral reaches a maximum as we should expect, amounting in this case to about six amperes. That is due, of course, to the unbalanced voltages of the system produced by the unbalanced line capacitances acting in the series resonant circuit. There is an unusual opportunity at the junction point of this Y to connect conductors of high, low and medium capacitance to ground, one from each branch of the Y, and so to improve the balance of the system without the expense of transpositions. Of course, if the branches of the Y are very different in length, this scheme would not work so well, unless the excess lengths of two branches over the third were transposed. At any rate, a considerable improvement would seem to be practicable at slight expense. Improved balance would, of course, enable the coil to be operated closer to the resonance adjustment without excess current under normal conditions.

H. W. Smith: In regard to the question of grounding the neutral of power systems, it should be pointed out that the engineers of the Westinghouse Company have consistently advocated this from the early days of power transmission.

For instance, P. M. Lincoln read a paper in 1907 on "The Grounded Neutral With and Without Series Resistance in High-Tension Systems," which he followed in 1909 with a

paper on "Protection of Electrical Equipment" in which he stated "It is my opinion that so far as protection to apparatus is concerned, the advantages of grounding the neutral very much outweigh the disadvantages and if protection to apparatus alone were to be considered I would have no hesitation in recommending a solidly grounded neutral system."

The experience of transmission companies is recorded in the files of A. I. E. E. in such papers as: 1914—The Experience of the Pacific Gas & Electric Company with Grounded neutral by Messrs. Jollyman, Downing & Baum; 1916—Report of of the Transmission Committee; 1919—Grounding The Neutral of Generating and Transmission Systems by H. R. Woodrow; Grounded Neutral Transmission Lines by W. E. Richards. They have led towards a general adoption of the grounded neutral.

I believe the operating companies, as regards this question of grounded neutral, should be divided into three classes: 1. Large metropolitan companies transmitting at generator voltage mostly through underground cables. 2. Medium voltage systems transmitting at 22, 33 or 44 kv. These systems often do not involve a large kw. capacity, but there is a large mileage of lines covering large districts. These systems often distribute at these voltages, rather than transmit; 3. High-voltage systems 66 kv., 88 kv., 110 kv., 132 kv., 154 kv., 165 kv., and 220 kv.

The general practise in class 1, is to ground the neutral. This was done quite early in the art, for example on the Manhattan Railway in New York about 1904.

A severe cause of trouble which was theoretically investigated by Dr. Steinmetz in his paper "High Power Surges in Electric Distribution Systems of Great Magnitude" (TRANS. 1905), led to the grounding of the neutral through a 6-ohm resistance (1000 amperes for two minutes).

As mentioned by Mr. Dewey, these systems can be:

(1) Grounded solidly; (2) Grounded through low resistance to pass currents in case of ground of such magnitude to operate relays set for short current protection; (3) Grounded through higher resistance to limit the current and prevent excessive burning of cable in case of ground.

This latter system involves a special system of ground relays the expense of which many companies have not seen fit to incur.

Satisfactory systems of ground relays have been developed for this use and are available for those companies which desire to use them.

Exact data showing the proportion of cable faults which are grounds and those which start as short circuits would be a welcome contribution to our information and help us to decide whether such ground relays should be used.

As pointed out, if it is desired to apply differential protection to generators to disconnect them in case of a ground on winding, it is necessary to ground the neutral of one or more generators.

In regard to the design of grounding resistors I believe it is safe to work up to a maximum temperature of 600 deg. cent. It should be pointed out that working through this range there is a considerable increase in the value of the resistance probably around 50 per cent, so that a resistor which was 5 ohms when cold would be around $7\frac{1}{2}$ ohms at the end of the time interval for which it was designed.

In regard to the time for which the grounding resistor should be designed there are a number of points to be considered. If there are a number of feeders in parallel feeding a substation, in the case of a ground occurring in that substation or beyond, the ground current will divide up so that the relays will probably not trip out the lines carrying the ground current and the total ground current through the resistor may burn it out. The resistor, therefore, in a case like this should have a long time element or should be protected by thermal relays which will either short-circuit or open-circuit the resistor when it reaches a dangerous temperature.

In regard to systems of the second class. In many cases the neutral is grounded at several points through a resistance. There

is no doubt that as these systems grow they will reach a point where it is essential to ground the neutral. There are however a number of systems with single-loop transmission lines having customers tapped at intervals which hesitate to ground the neutral on account of interruption of service. In many cases these systems are not properly equipped with relays and oil circuit breakers. All extensions to such systems should be made so that adequate relay and circuit breaker protection are installed with duplicate lines to important load centers so that a grounded neutral system can be installed as soon as possible.

In regard to considerations fixing the size of resistance. If no resistance or a low resistance is used to ground the neutral, then any ground will seriously distort the voltage triangle, and affect synchronous apparatus on the system.

Tests have been made which show that the factor to be considered is the positive phase sequence component of the voltage at the terminals of the apparatus considered. If this voltage is less than 70 per cent of normal voltage it is probable that no trouble will be experienced from apparatus dropping out of step provided they are not overloaded and have full excitation. Tests have shown that the value of ground resistance to give this drop in voltage is approximately a resistance which allows double full-load current to flow to ground, that is

$$\frac{\text{phase voltage}}{R} = 2 \times \text{F.L. current, so that if the ground current}$$

does not exceed twice full-load current, synchronous apparatus should generally stay in step.

H. M. Trueblood: I have merely a brief suggestion to offer with regard to the three cases of doubtful operation of

FIG. 1

the Petersen coil which are mentioned in the paper by Messrs. Oliver and Eberhardt. They are referred to on page 907 of that paper and further in Table I, under the dates of July 7 and August 25, 1922, and February 23, 1923. It is rather interesting, I think, that in each of these three cases what was observed was a flashover on the 44-kv. bus, and, connected with that disturbance in some way, was an operation of line switch 206 between the line and the bus.

In the diagram, the Fig. 1, 1, 2, and 3 represent the three poles of a switch and the condensers C_{10} , C_{20} and C_{30} represent the direct capacities of the three phases to ground. X is the Petersen coil. Let us suppose that one of the three switch contacts, *e. g.*, No. 3 opens up while the other two remain closed, as might occur, for instance, if, through some defect in the switch mechanism, the three poles are not operated simultaneously. In this case the capacity in what has sometimes been called the "series resonant circuit", consists of C_{10} and C_{20} in parallel, plus an additional capacity equivalent to the direct capacities of phases 1 and 2 to phase 3 in parallel, in series with C_{30} . Now, if the reactance in X is larger than is correct for resonance with all three poles of the switch closed, a condition of resonance with pole No. 3 open may be approached. This will tend to produce high voltages across the inductance and

also across the capacity of the series circuit. If the reactance of the Petersen coil exceeds the correct value for resonance under normal conditions by the appropriate amount, it will, of course, resonate exactly with the capacity of the system to ground with one pole of the switch open. In this case there will be nothing to limit the rise of voltage except the system losses.

In comparing the data in the table on page 906 of the Oliver-Eberhardt paper with Figs. 21 and 22 of Mr. Lewis' paper, I have been led to the conclusion that the system described has been operated with a reactance on the Petersen coil in excess of the proper value for resonance under normal conditions. *E. g.*, the curves of Fig. 22 of Mr. Lewis' paper indicate that for exact resonance about 980 ohms is required in the reactor. From the table in the other paper, however, it appears that the reactance actually used for the system arrangement referred to is 1207 ohms. The excess reactance is thus about 23 per cent in this case. The same condition may be traced from a comparison of Fig. 21 of Mr. Lewis' paper with the data in the Oliver and Eberhardt paper. The figure shows that about 1410 ohms in the reactor would be correct for lines 1, 2 and 4. The value used, however, is apparently 1735 ohms. The excess is again about 23 per cent.

If I am correct in inferring from these data that the system has been operated with excess reactance of this magnitude in the Petersen coil, I think that the explanation of the excessive voltages that have been observed may be as I have indicated. The condition could, of course, be corrected by decreasing the reactance used.

R. D. Evans: Mr. Oliver and Mr. Eberhardt have presented the results of the operating experience with the Petersen coil installed on the Alabama Power Company's system. In comparison with the previous year's operation as a solidly grounded neutral system, the Petersen coil installation resulted in decreased interruptions due to line insulator flashovers caused by lightning, and increased interruptions in the remainder of the system, apparently due to excess voltages causing bus flashover and transformer trouble. Both of these results might have been anticipated, as previous discussions have pointed out their probability. That excess voltages may occur with the Petersen coil is borne out by the flashovers on the 44-kv. bus at Lock 12, which followed the opening of a circuit breaker between the coil and the transmission line. These flashovers may have been due to the non-simultaneous opening of the 3 poles of the circuit breaker, which condition is one that may produce excessive voltages with the Petersen coil system.

The operating record shows that in a number of cases an insulator flashover produced an arc lasting for two seconds, when the neutral was grounded by the circuit breaker. All of these conditions were not produced by dead grounds, as in some cases the line could be closed back in service o.k. The operating log for these cases is marked "Correct Operation" though the Petersen coil did not suppress the arc, and it is doubtful if it would after the arc had persisted for two seconds. In the arcing test made by Mr. Lewis, it is to be noted that the arc was maintained for 14 cycles for a reactor setting of 80 per cent normal, and that the arc resembled "a power arc". The arcing test and the maintenance of an arc for two seconds under service conditions indicates that the limits for the satisfactory operation of the Petersen coil are being approached for a system as extensive as this section of the Alabama Power Company's 44-kv. system.

On account of the high voltages produced by switching operations, which led to interruptions, Mr. Oliver and Mr. Eberhardt have concluded that all switching operations should be performed with the neutral solidly grounded. In view of this fact, and because of the number of conditions where the arc was not suppressed by the Petersen coil, it appears very desirable to supplement the Petersen coil with equipment to solidly ground the neutral.

Mr. Lewis is of the opinion that the field of the Petersen coil will probably be limited mainly to isolated neutral systems, whose operation is not satisfactory, but on which for some reason it is not wished to solid-ground the neutral. In view of the reasons given above for supplementing the Petersen coil with grounding equipment, it would appear that a change-over from a free neutral system would require that the system be designed for solidly grounded neutral operation, including the installation of relays and circuit breakers, in addition to the Petersen coil, auxiliary grounding circuit breakers and relay. It is to be noted that Mr. Lewis concludes that for the present, at least, the Petersen coil is not of general application, but limited to comparatively low-voltage lines of relatively short length.

C. L. Fortescue: In 1914 I presented a paper (Proc. May 1914 p. 771) grounding of the neutrals of systems, above 44,000 volts. At that time the General Electric made an announcement of their new policy with respect to grounding neutrals of high-voltage systems. It is interesting to see that about a decade later we are investigating the results of this agreement in the engineering policy of the two large electric manufacturing companies and the results are quite gratifying.

Mr. Dewey seems to imply that at that time there was a certain amount of uncertainty in the minds of engineers as to whether to ground or not to ground. However, my impressions at that time were that the evidence in favor of grounding was quite convincing. The basis of the evidence on which this conclusion was based was well borne out by the experimental work of Mr. Faccioli. The theory on which most of us worked at that time was that an ungrounded system was free to oscillate at its natural period with very little damping, and therefore in extensive systems surges set up would be reflected, superimposed, etc., causing high-voltage disturbances. At the present time with the very extensive high-voltage systems that are in contemplation, there are additional very weighty reasons for grounding, and also for grounding at many points.

For example, let us consider a 750-mile transmission line of 440-kv. I have taken this length because it is not outside future possibilities, and happens to be about one-quarter wave length of 60 cycles. If such a line were ungrounded a ground near the generating station would be equivalent to a potential of 127,000 volts impressed on an open line 750 miles long, and having exceedingly low loss. The result would be, to quote from a recent paper by Mr. Peck, "Instability will be noticed at distances considerably less than this. At no load and very low generator voltages, the power of such a line would be limited, in fact, only by the losses." Therefore, if a high-voltage line of the kind in contemplation were not grounded, we would have in the case of ground on one line exceedingly high-voltages at the further end.

A transmission system grounded at many points is on the other hand equivalent to a number of short-circuited transmission lines, and the surge potentials that can be obtained due to disturbance at immediate points are very limited in value.

In regard to the effect on telephone systems, these will best be taken care of by keeping as far away from such high-voltage transmission lines as possible. Quick operating relays may afford a measure of relief, but the power companies and the telephone will have to depend much on co-ordination.

The Petersen coil seems to have found the place which was predicted for it. Personally the writer believes that the use of grounding resistance, of value below the critical value, will be found more satisfactory.

As to how to ground, high-voltage systems above 110,000 should be solidly grounded. In general this should apply for still lower voltages, say, down to 66,000 volts. On very high-voltage systems, all distributing points and the substation at the end of all feeders of high voltage should be grounded.

Of course, no system can actually be solidly grounded, but as far as the transformers are concerned if their neutral points are solidly connected to ground, the potential stresses they will

be subjected to will be a minimum. This will also permit graded insulation which in the case of very high-voltage transformers makes a very substantial reduction in cost.

J. A. Johnson: There are two or three points in connection with this matter of grounding which I feel should be perhaps brought out a little more in detail than have been mentioned.

In the first place, systems differ very greatly in characteristics, and I very much doubt whether any one system of grounding will ever be found satisfactory for all systems; systems which have large exposure to communication systems may always require high-resistance grounding for the limitation of interference. In that connection engineers I think, as well as other people, are prone to follow the line of least resistance and when they run against a problem which requires an immediate solution, they usually jump to something that looks pretty obvious and if it works, why, they stick to it until something else comes up that causes them to change, and possibly some situation of that sort may be responsible for some of the systems using high-resistance grounding.

Now, in connection with systems, more particularly those operating at generator voltage: I think that we sometimes lose sight of how the tools which we have to work with influence our practice, and in that connection I want to bring to your notice the connection between the characteristics of our modern relays, referring especially to the so-called induction type, having the inverse-time characteristic, and the question of grounding.

In using these relays for short-circuit protection, on account of the fact that short-circuit currents usually exceed normal currents by so great an amount as they do, it is very difficult to apply these relays in such a way as to take advantage of their inverse-time-current characteristic, and they become in most cases simply current relays, operating at their minimum time, so that for selective action, we have to depend mostly on the time adjustment rather than on the current adjustment.

Now, when we come to the question of grounding, one of the objects of grounding, or at least one of the advantages that we get from grounding, is the ability to isolate a circuit that is in trouble with a minimum of interference with the operation of the system. The fact that a system will stand short circuits, so far as the apparatus goes, is to my mind, no excuse for subjecting it to unnecessary short-circuit currents because large currents are bound to interfere more or less with operation, even though they do not injure the apparatus.

Now, suppose you have a simple radial system, consisting of some sort of a center of distribution, with various generating sources feeding into it, and various lines feeding out of it. And let us suppose that we get a ground on a feeder. If we ground our neutrals at all of these generating sources through moderately high resistances, we will then get a moderate ground current going over each of these circuits, but all concentrating into the feeder that is in trouble, and if we use a ground relay separate from our overload protection; we can choose that relay of such a capacity or we can choose our resistances of such a value as to produce a ground current which comes within the normal range of the relay and take advantage not only of the current characteristic but also of the time characteristic of the relay. We can thereby trip out the faulted circuits without danger to the rest of the system better than we can if we depend solely on the over-current relays for tripping out ground faults.

L. F. Blume: The excellent performance of the Petersen earth coil, as recorded in the two papers presented today is a gratifying confirmation of the sound theory upon which it is based. Although it was clear theoretically that such a coil should function to reduce the current flowing in a line fault to ground, it nevertheless could not be foretold that it would prove so effective in disposing of the line fault and thereby materially lessen interruptions in service.

The flashover which resulted in the breakdown of the busses

is probably very excellently explained by Mr. Trueblood and shows the effect of extreme dissymmetry in the lines, dissymmetry of the three lines being very extreme due to the breaking of the line at the point of the operation of the switch.

It is perfectly feasible by having fifty per cent untuning, combined with this combination of circumstances, to get serious resonance of this voltage to ground, and at normal frequency. Of course, under those conditions very excessive voltage will be obtained. The remedy for that however is very simple. All that one need do is to be sure that this coil is untuned on the other side of resonance, by making the resistance a little less than for the normal resonating conditions. The voltages which you will get under this particular condition of operation will be only moderate, so if that is the explanation of the flashovers from the busses, I think that a simple adjustment of the coil will take care of the trouble.

It seems to me that the records given in the two papers show that the operation of the coil could be improved by introducing more resistance. The coil as designed has very little resistance, because it was designed to operate continuously with a fork on the line.

Now, if it is to be operated for intermittent duty only, it is perfectly feasible to introduce considerable inherent resistance in the coil which will be very effective in preventing danger due to serious over-voltage, resonance, dissymmetry. It will reduce the residual current under such conditions as shown by the oscillograms considerably.

H. L. Wallau: We have been operating for about eighteen years a moderate voltage system with a grounded neutral and the results of our experience, confirms Mr. Johnson's statements to a very wide degree. I wanted to comment in that connection on a statement made by Mr. Smith: If I understood him rightly he said that the thermal capacity of the resistance might be a considerable factor where a ground took place beyond a substation bus, which bus was fed by a number of lines in parallel, because the ground current would be divided between these lines. It seems to me that would only be the case if the breaker in the outgoing line was set so high that it could not trip at a reasonable speed with the total ground current that must flow through it, due to the current flowing into the fault beyond the substation bus.

You might have but a few hundred amperes in the individual supply lines, but the total current would flow in the final line on which the ground developed, and if the time of tripping is reduced to a minimum, you need not have such a large thermal capacity.

Another point brought up by Mr. Atkinson was that the cables with equal thickness of insulations, conductor insulation equal to belt insulation were not quite as effective as cables would be designed with a greater belt thickness. It has been our experience that since we changed over from a six by six thirty-seconds insulation on 11-kv. cables to eight by two, thereby increasing the insulation between phases and decreasing from phase to ground, we have had considerably less cable trouble, and I believe although I am not positive, less trouble from phase to ground.

W. I. Slichter: There is a practical condition in connection with the tuning and detuning of the circuit which seems to me has been overlooked, namely that the step-down transformers at the receiving end of the transmission line will probably remain in circuit and they afford a circuit between phases which it would seem would prevent the detuning. I wish to ask whether this is not the case in practical operation.

W. W. Lewis: The discussion has brought out a number of constructive suggestions. Mr. Ferris suggests transposing the three banks of the Y at Vida; Mr. Trueblood gives an explanation of the possible cause of the three cases of over-voltage which resulted in bus flashover and suggests a reduction in the reactor ohms to remedy the situation; Mr. Blume suggests increasing the resistance of the coil to reduce the residual current and increase the damping effect. All of these suggestions will prob-

ably be acted upon within the present year and will no doubt be reflected in an improved operating record.

As to Mr. Evans' statement that the use of the coil resulted in increased interruptions in the remainder of the system, apparently due to excess voltages causing bus flashover and transformer trouble: I would call attention to the fact that the 343 minutes outage due to transformer trouble in January was the result of a burned out transformer coil. This transformer had been subjected to repeated short circuits during the progress of switch tests in November and December 1921 and January 1922, which finally broke down the transformer winding. The Petersen coil was not in circuit during the switch tests but the neutral of the transformer bank was dead grounded. The Petersen coil can only be charged with the three insulator flashovers which caused a total outage of 229 minutes.
